Submit manuscripts (3 copies) to Editor, *Journal of Applied Physics*, Argonne National Laboratory, Bldg. 203, Room R-127, 9700 South Cass Avenue, P.O. Box 8296, Argonne, IL 60439-8296.

Physics Auxiliary Publication Service (PAPS) and/or Electronic PAPS (E-PAPS): For a nominal fee, authors may submit material that is part of and supplemental to a paper, but is too long to be included in the journal. PAPS deposits may be on paper or in electronic media, and can include text, data in graphic or numeric form, computer programs, etc. Retrieval instructions are footnoted in the related published paper. Direct requests to the editor.

The *Journal of Applied Physics* (ISSN: 0021-8979) is published semimonthly by the American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Second-class postage paid at Woodbury, NY, and additional mailing offices. POSTMASTER: Send address changes to *Journal of Applied Physics*, AIP, 500 Sunnyside Blvd.,

The *Journal of Applied Physics* is the American Institute of Physics' (AIP) archival journal for significant new results in applied physics. The journal publishes articles that emphasize understanding of the physics underlying modern technology. There are two issues per month. The subject coverage includes, but is not limited to, experimental or theoretical physics applied to all aspects of materials: for example, charge and mass transport, superconductivity, magnetism; surfaces, interfaces, thin films, crystal lattice defects; electrical, optical, magnetic, and structural properties; processing; ion implantation. Materials covered include semiconductors, superconductors, metals and alloys, amorphous materials, and oxides. Other important topics are: electrical, optical, and magnetic devices; optics and lasers; nonlinear optics; electrical discharges; acoustics. The Proceedings of the Annual Conference on Magnetism and Magnetic Materials is a regular feature. *Applied Physics Reviews* is a series of occasional review articles on similar subjects.

Publication Charge: To support the cost of wide dissemination of research results through publication of journal pages and production of a database of articles, the author's institution is requested to pay a page charge of \$55 per page (with a one-page minimum) and an *article charge* of \$20 per article. For any regular, published article that exceeds 10 journal pages, a mandatory \$150 page charge will be added for each page in excess of 10 pages. For Errata the minimum page charge is \$10, with no article charge.

Subscription Prices* (1996)

	U.S.A. & Poss.	Can., Mex., Central & S. Amer. & Caribbean	Foreign Surface Mail	Air Freight Europe, Asia, Africa & Oceania	Optional Air Freight
Members [†]	\$210	\$295	\$295	—	\$480
Nonmembers	\$2045	\$2130	—	\$2315 [‡]	—

*The journal is available on microfiche at \$210 per year to members and \$2045 per year at the nonmember rate.

[†]AIP Member and Affiliated Societies. [‡]Includes air freight service.

Back-Number Prices: 1996 single copies: \$95. Prior to 1996 single copies: \$26 for members; \$95 for nonmembers. Prices for conference supplements available on request.

Subscription, renewals, and address changes should be addressed to *AIP Circulation and Fulfillment Division (CFD)*, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Allow at least six weeks advance notice. For address changes please send both old and new addresses and, if possible, include a mailing label from a recent issue.

Claims, Single Copy Replacement and Back Volumes: Missing issue requests will be honored only if received within six months of publication date (nine months for Australia and Asia). Single copies of a journal may be ordered and back volumes are available in print or microform. Members—contact AIP Member Services at (516) 576-2288; (800) 344-6901. Nonmember subscribers—contact AIP Subscriber Services at (516) 576-2270; (800) 344-6902; Internet: subs@aip.org.

Page Charge and Reprint Billing: Contact: AIP Publication Page Charge and Reprints—CFD, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; (516) 576-2234; (800) 344-6909.

Copying: Single copies of individual articles may be made for private use or research. Authorization is given (as indicated by the Item Fee Code for this publication) to copy articles beyond the use permitted by Sections 107 and 108 of the U. S. Copyright Law, provided the copying fee of \$10 per copy per article is paid to the Copyright Clearance Center, 222 Rosewood Drive, Danvers, MA 01923, USA. Persons desiring to photocopy materials for classroom use should contact the CCC Academic Permissions Service. The Item Fee Code for this publication is 0021-8979/96 \$10.00.

Authorization does not extend to systematic or multiple reproduction, to copying for promotional purposes, to electronic storage or distribution, or to republication in any form. In all such cases, specific written permission from AIP must be obtained.

Permission for Other Use: Permission is granted to quote from the journal with the customary acknowledgment of the source. To reprint a figure, table, or other excerpt requires the consent of one of the authors and notification to AIP.

Requests for Permission: Address requests to AIP Office of Rights and Permissions, 500 Sunnyside Boulevard, Woodbury, NY 11797-2999; Fax: 516-576-2327; Telephone: 516-576-2268; Internet: rights@aip.org.

Publisher Item Identifier: A Publisher Item Identifier (PII) has been adopted by AIP and other publishers to provide unique and concise identification of individual published documents. The PII appears at the end of the abstract of each article. The PII should be included in all document requests for copies of the article.

Document Delivery: Copies of articles can be ordered for \$15 per copy from the AIP/Member Society document delivery service, "Articles in Physics," 1722 Gilbreth Road, Burlingame, CA 94010-1305; Fax: 415-259-6044; Telephone: 800-480-PHYS (in U.S. and Canada), or 415-259-6002; Internet: articles@aip.org.

Reprints: Reprints can be ordered with or without covers only in multiples of 50 (with a minimum of 100 in each category) from AIP, Circulation & Fulfillment/Reprints, 500 Sunnyside Boulevard, Woodbury, NY 11797-2999; Fax 516-349-9704; Telephone: 800-344-6909 (in U.S. and Canada), or 516-576-2234.

Microform: *Journal of Applied Physics* is available on microfiche issued at the same frequency as the printed journal and annually on microfilm. A microform catalog is available from AIP, Circulation & Fulfillment/Single Copy Sales, 500 Sunnyside Boulevard, Woodbury, NY 11797-2999; Fax: 516-349-9704; Telephone: 800-344-6908 (in U.S. and Canada), or 516-576-2277.

Online Availability: Abstracts of journal articles published by AIP and Member Societies (and several other physics publishers) are available in the SPIN database via the AIP online

**FORTIETH ANNUAL CONFERENCE
ON
MAGNETISM AND MAGNETIC MATERIALS
November 6–9, 1996
Philadelphia, Pennsylvania**

Sponsored by

The American Institute of Physics
The Magnetics Society
of the
Institute of Electrical and Electronics Engineers

In Cooperation with

The Minerals, Metals, and Materials Society
The American Society for Testing and Materials
The Office of Naval Research
The American Ceramic Society

The Conference is especially grateful to

THE OFFICE OF NAVAL RESEARCH
for its support of the expenses of foreign and interdisciplinary speakers

**CONTRIBUTORS TO THE 40TH ANNUAL CONFERENCE ON
MAGNETISM AND MAGNETIC MATERIALS**

The 40th Annual Conference on Magnetism and Magnetic Materials wishes to express appreciation to the following Corporations for their generous support.

BASF Magnetics GmbH
Crucible Magnetics
Eastman Kodak Company
F. G. Jones Associates, Ltd.
Fujitsu, Ltd.
General Electric Company
Hitachi, Ltd.
IBM Corporation
Innovative Instrumentation, Inc.
KJS Associates Inc.—Magnetics Engineering

Lake Shore Crytronics, Inc.
Magnequench
Mitsubishi Chemical Corporation
NEC Corporation
The Permanent Magnet Co., Inc.
Quantum Corporation
SONY Corporation
TDK Corporation
3M
Toda Kogyo Corporation

PREFACE

The Conference on Magnetism and Magnetic Materials held its 40th anniversary meeting, November 6–9, 1995 in Philadelphia, Pennsylvania. The history of the Conference was highlighted in a special session of remembrances by three members of the original 1955 MMM organizing committee, W. (Bill) Meiklejohn, John Osborn, and J. E. (Jack) Goldman, followed by a champagne reception. Over 60 magneticians who had attended the early meetings participated in these activities. Another session with historical significance was the Commemorative Symposium on Neutron Scattering which featured talks by the 1994 Physics Nobel Laureates, Clifford G. Shull and Bertram Brockhouse. The scientific program of the meeting ranged broadly from fundamental to applied topics. Symposia were organized on High Performance Permanent Magnets, 10 Gbit/in.² Magnetic Recording, Giant and “Colossal” Magnetoresistance, Magnetic Nanostructures, Spin Tunneling and Injection, and unusual Fe magnetism as seen in Fe₁₆N₂ and fcc-Fe. A total of 958 papers were presented; selected from 1192 submitted abstracts.

Before thanking all of the people who contributed to the success of the Conference, I would like to take the opportunity to describe briefly how the Conference is organized. The MMM Conference was founded 40 years ago to bring together for mutual discussions those pursuing basic research and applications in magnetism. A volunteer advisory committee of 30 members, half appointed by the IEEE Magnetics Society and half by the American Institute of Physics (the sponsoring societies) has responsibility for all financial, administrative, and technical aspects of the conference. Individual jobs are filled by volunteers from the magnetism community, with the able assistance of the professional conference managers at Courtesy Associates and the publications staff at AIP. New volunteers are always sought, and the aim is to make the Conference management as democratic and as broadly representative of the community as possible. The community served by MMM is truly international as reflected by the 1002 attendees at the 1995 conference of which 278 registrants and 74 students were from outside the US, and includes many students and postdoctoral researchers.

My role as General Chairman gave me the unique pleasure of leading a group of talented and creative individuals, each of whom independently did an outstanding job. Their names are listed in these proceedings and I offer each my heartfelt thanks. I would also like to thank Israel Jacobs for organizing the historical activities to remind us how far we have come in 40 years, and let us marvel at the continuing vitality and fascination of the field of magnetism.

Kristl Hathaway
General Chairman
MMM '95

Symposium on 10 GB/in.² Magnetic Recording

- 4485 Approaches to 10 Gbit/in.² recording (invited)
- 4491 Impact of new magnetoresistive materials on magnetic recording heads (invited)
- 4496 Media for 10 Gb/in.² hard disk storage: Issues and status (invited)
- 4502 Signal processing for 10 GB/in.² magnetic disk recording and beyond (invited)
- 4508 Head/disk tribology: Toward 10 Gb/in.² (invited) (abstract)

Kevin D. Fisher, Cory S. Modlin

B. Marchon

Interlayer Coupling

- 4509 Quantum oscillations of properties in magnetic multilayers (invited)
- 4515 Calculated spacer-layer Friedel oscillations in Co/Cu(001)
- 4518 Interface alloying at Fe/Cr interfaces and its role in exchange coupling, angular resolved Auger electron, magneto-optic Kerr effect, and Brillouin light scattering studies (invited)
- 4524 Suppression of biquadratic coupling at the Cr Néel temperature in Fe/Cr(001) superlattices (invited) (abstract)
- 4525 Interlayer thickness Dependence of the strong 90° coupling in epitaxial CoFe/Mn/CoFe trilayers
- 4528 Dependence of the interlayer exchange coupling on the constitution of the magnetic layers
- 4531 Domain structure and anisotropy of exchange coupled Co/Cr/Fe multilayers (abstract)
- 4532 Magnetic coupling in Co/face-centered-cubic Fe/Co sandwiches

R. K. Kawakami, Ernesto J. Escorcia-Aparicio, Z. Q. Qiu

Colossal Magnetoresistance in Perovskite Oxides I

- 4535 Transport and magnetism correlations in thin-film ferromagnetic oxides
- 4538 Colossal magnetoresistance in the antiferromagnetic La_{0.5}Ca_{0.5}MnO₃ system
- 4541 Lattice effects on the magnetoresistance in doped manganese perovskites (abstract)
- 4542 Electrical conductivity in ferromagnetic perovskite structures
- 4545 Response to an electric field of Nd_{0.7}Sr_{0.3}MnO₃ films in a MOSFET configuration (abstract)
- 4546 Magnetotransport and hysteretic behavior in epitaxial La_{0.67}Ca_{0.33}MnO_{3-δ} films
- 4549 Magnetoresistance and magnetic properties of La_{1-x}□_xMnO_{3-δ} thin films

T. R. McGuire, A. Gupta, P. R. Duncombe, M. Rupp, J. Z. Sun, R. B. Laibowitz, W. J. Gallagher, Gang Xiao

- 4552 Superparamagnetic behavior and giant magnetoresistance in oxygen deficient $R_{0.67}Sr_{0.33}MnO_z$ ($R=Nd, Pr$) epitaxial films (abstract)
- 4552 Role of lattice distortions in the transport property of $R_{0.7}Me_{0.3}MnO_3$ ($R=Pr, Nd, La$ and $Me=Ba, Sr, Ca$) (abstract)
- 4553 The effect of disorder and fluctuations on the magnetotransport of a double-exchange ferromagnet (abstract)
- 4553 Ozone assisted, block-by-block, molecular beam epitaxy of $La-M-Mn-O$ ($M=Ca, Ba, Sr$) thin films and $La-M-Mn-O/Dy-Ba-Cu-O$ multilayers (abstract)
- 4554 Transport properties and magnetic behavior of $La_{1-x}Sr_xMnO_3$ single crystals (abstract)
- 4555 Density-functional studies of the electronic structure of the perovskite oxides: $La_{1-x}Ca_xMnO_3$
- 4558 Electron spectroscopic studies of colossal magnetoresistance material $La_{1-x}Ca_xMnO_3$

Soft Ferrites and Alloys I

- 4561 Cation distribution in NiZn-ferrite films determined using x-ray absorption fine structure
- 4564 Possible nearly loss-free ferrimagnetic resonance in small samples
- 4567 Anomalous low dimensional system: Study of magnetism and electrical conductivity in $Na_2Ru_4O_{9-\delta}$
- 4570 Growth of epitaxial films of iron oxide, nickel oxide, cobalt oxide, strontium hexagonal ferrite, and yttrium iron garnet by laser ablation (abstract)
- 4570 Resolution of conflicts concerning $Fe_{16}N_2$ (abstract)
- 4571 Influence of the plastic anisotropy on the magnetic properties of a nonoriented 3% silicon iron
- 4574 Magnetic properties of 3%Si-Fe thin sheets annealed in Ar atmosphere (abstract)
- 4575 Power losses in thick steel laminations with hysteresis
- 4578 High temperature magnetic properties of 49%Co-2%V-Fe alloy
- 4581 Effect of nucleating layers on the soft magnetic properties of multilayer permalloy films

Hard Magnet Nitrides, Carbides, and Hydrides

- 4584 A spin reorientation in $Pr_2Fe_{17}D_3$ as revealed by Mössbauer spectroscopy
- 4587 Neutron diffraction and Mössbauer spectral study of the $Nd_2Fe_{16}TiC_x$ solid solutions
- 4590 Mössbauer study of permanent-magnet $R_2Fe_{17-x}M_xC_y$ compounds
- 4593 Crystal field induced anisotropy in rare earth intermetallics as studied by ^{155}Gd Mössbauer spectroscopy
- 4596 Study of the nitrogen diffusion mechanism in R_2Fe_{17}

- 4599 Nuclear magnetic resonance study of expanded lattice permanent magnet nitrides and carbides at high pressure
- 4602 Band theoretical investigation of the Curie temperatures of modified R_2Fe_{17} -based intermetallic compounds
- 4605 Metastable RFe_7 compounds (R =rare earths) and their nitrides with $TbCu_7$ structure
- 4608 High field magnetization isotherms of the $Pr_2Fe_{17}D_5$ system
- 4611 Structural and magnetic properties of rapidly quenched $(R,Zr)(Fe,Co)_{10}N_x$ ($R=Nd,Sm$)
- 4614 Aligned high magnetization $Nd(Fe,Co,Mo)_{12}$ films nitrided by N ion implantation
- 4616 Magnetic and phase transformation studies in $Nd_{15}DyFe_{75}(C,B)_9$ cast alloys
- 4619 Characteristics of $Sm_2Fe_{17}C_x$ compounds prepared from ball-milled blends of Sm_2Fe_{17} and graphite
- 4622 Exchange and crystal-field interactions in $R_3(Fe,Ti)_{29}$ and $R_3(Fe,Ti)_{29}N_y$ ($R=Nd,Sm$)

Critical Phenomena I

- 4625 Magnetic ordering in clustered Fe-based materials synthesized from laser plasma (abstract)
- 4626 Magnetization processes of free- and fixed-single-crystal antiferromagnets
- 4629 Dynamics of quantum spin systems in dimer and valence-bond-solid ground states stabilized by competing interactions
- 4632 Spin correlation functions in random-exchange $s=1/2$ XXZ chains
- 4635 Rotational hysteresis and self-organized criticality in magnetic recording media
- 4638 Quantum correction to the BKT transition for 2D easy-plane antiferromagnets
- 4641 Homogeneous magnetization dynamics below T_c of EuO: Effects of spin waves and anisotropy
- 4644 Concentration-dependent critical behavior in dilute ferromagnetic $Fe_{1-x}As_x[S_2CN(C_2H_5)_2]_2Cl$

Magnetoelastic Effects

- 4647 Magnetovolume effects of $MnAs_{1-x}Sb_x$
- 4650 Transmission electron microscopy of Terfenol-D crystals
- 4653 Propagation and reflection properties of magnetoelastic wave in FeSiB amorphous wire
- 4656 Anomalous compressibility and magnetovolume effects in $Ce_3(FeTi)_{29}$
- 4659 Magnetostriction and thermal expansion measurements on $FeRh_{1-x}Pt_x$ alloys

Approaches to 10 Gbit/in.² recording (invited)

M. H. Kryder, W. Messner, and L. R. Carley

Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3890

The areal density of manufactured magnetic disk drives is currently advancing at a rate of about 60% per year. Assuming this continues, an areal density of 10 Gbit/in.² will be reached sometime shortly after year 2000. In this paper, the characteristics of a disk drive with 10 Gbit/in.² density and the requirements that such an areal density places upon the component technologies necessary to make such a drive possible are discussed. It is projected that smooth, high coercivity and fine grain media, high moment thin film write heads, spin-valve read heads, advanced signal processing techniques, and improved servo systems will make it possible to achieve this goal using flying heads and longitudinal recording. © 1996 American Institute of Physics. [S0021-8979(96)28508-8]

I. INTRODUCTION

Magnetic recording has advanced approximately 500 000 times in areal density since its introduction into magnetic disk drives by IBM in 1957, and is approaching 1 Gbit/in.² in manufactured products. Now, at the 1995 Magnetism and Magnetic Materials Conference, a group of us have been asked to describe how 10 Gbit/in.² recording density is going to be achieved. The purpose of this paper is give an overview of what technologies need to be developed to enable it to occur. There are several other papers in this session, which go into considerably more detail about the individual component technologies, and it would be surprising if this overview and the other papers agreed in all areas. It is probably best that they do not, because there are still many unanswered questions, and if we all agreed, the chances are we would be missing some of the best solutions.

II. 10 Gbit/in.² DRIVE CHARACTERISTICS

Before considering the enabling technologies, let us consider what sort of a drive a recording density of 10 Gbit/in.² would make possible. An approximately linear extrapolation of both bit and track density from today's drives suggests that the track density will be about 1000 tracks/mm (25 000 tpi) and that the linear density will be about 16 000 bits/mm (400 000 bpi). At the present time, this linear extrapolation is about what is expected, but the actual tradeoff between track and bit density will be decided by factors such as the servo accuracy which is achieved and the media signal-to-noise ratio.

Using zone recording on the disk, a density of 10 Gbit/in.² would enable one to pack about 2.5 Gbytes on a single 1.3 in. (3.3 cm) disk. If the disk were spun at 10 800 rpm, the linear bit density of 16 000 bits/mm would enable a data rate of 18.4 Mbytes/s off the inner track and nearly twice that off the outer track. Although the 1.3 in. H. P. Kittyhawk may have been ahead of its time, we can expect such small drives in the future, because such data rates will be a challenge for the channel electronics, and the data rate off a 3.5 in. disk will be proportionately higher.

Of course, the small disk size will reduce the access time. Smaller disks may be spun at higher velocities, because vibrations are less. This shortens the latency. At 10 800 rpm the average latency time (half way around the disk) is only 2.8 ms. In addition, the smaller disk diameter shortens the stroke of the actuator during a seek. Assuming an actuator with a force of 100 times the force of gravity the average (1/3 of full stroke) seek time would be 3.3 ms on a 3.3 cm disk. Although the data rate is climbing sufficiently rapidly that the channel electronics has a hard time keeping up, even *smaller disk size and faster spindle speeds don't help the access time nearly as much as computer engineers would like*. The above calculation suggests this situation is not likely to change.

III. SPACING LOSS AND TRANSITION PARAMETER

Before discussing the types of media and heads which might be used in a 10 Gbit/in.² disk drive, let us consider what requirements such densities place upon the head-medium spacing and the width of the recorded transition.

Taking into account the effect that a finite transition width and a finite media thickness has upon playback, the effective spacing loss, during readback for magnetic recording may be written as

$$\frac{d+a+\delta/2}{b} \times 27.3 \text{ dB}, \quad (1)$$

where d is the head to medium spacing, a is the Williams-Comstock transition parameter,¹ δ is the medium thickness, and b is the spacing between transitions.

In scaling from 1 Gbit/in.², which drives are approaching today, to 10 Gbit/in.², the linear density is expected to increase by about a factor of three. Thus, to maintain signal level, it is desirable that the quantities in $(d+a+\delta/2)$ be scaled down by about a factor of three. This linear scaling suggests that $(d+\delta/2)$ should be reduced to about 25 nm from the 80 nm used in the IBM 1 Gbit/in.² demonstration² and that the Williams-Comstock transition parameter,

$$a = [M_r \delta (d + \delta/2) / \pi H_c]^{1/2}, \quad (2)$$

should be reduced from a typical 38 nm for the 1 Gbit/in.² density to about 13 nm for 10 Gbit/in.²

Achieving 25 nm head-to-medium spacing will require that the media be extremely smooth and have very thin overcoats. Texturizing the disk surface to prevent stiction is unlikely to be used, except possibly in a restricted landing zone on the disk surface.³ It is believed that flying heads will be able to achieve such small head-medium spacings on smooth disks; however, an alternative approach is to use a lightly loaded contact recording head of the type proposed by Censtor.⁴

IV. MAGNETIC MEDIA

To achieve such a narrow transition parameter, not only must the head-media spacing be low, but low $M_r\delta$ media with high H_c must be used. Utilizing Eq. (2) and solving for H_c with $a=13$ nm, $(d+\delta/2)=25$ nm, and $M_r\delta=5\times 10^{-3}$ A (0.5 memu/cm²) which is believed to be appropriate for a spin-valve head, one obtains $H_c=235$ kA/M (3000 Oe).

In addition to being thin and having high coercivity, it is also necessary that the media have low noise. Mallinson showed a number of years ago that the media signal-to-noise power ratio was roughly equal to the number of independent magnetic particles being sensed at any one time by the recording head.⁵ For a thin film medium in which the grains extend through the medium thickness, this is approximately

$$\text{SNR} = 10 \log_{10} \frac{b \times W}{d^2} \quad (3)$$

where SNR is the signal-to-noise ratio, b is the minimum spacing between transitions, W is the trackwidth, and d is the grain size.

As is discussed below in the section on signal processing, it is not yet certain what type of coding will be used for these densities, and therefore it is not yet known what the minimum linear transition spacing, b , will be. For a 2/3 (1,7) run length limited (RLL) code, there are 1.33 bits per linear transition spacing, whereas, for a $d=0$, 8/9 rate code, there are 0.89 bits per linear transition spacing. For a linear density of 6000 bits/mm, assuming the 2/3 rate (1,7) code is used, $b=84$ nm (12 000 fr/mm), whereas, for the $d=0$, 8/9 rate code, $b=56$ nm (18 000 fr/mm). Assuming a SNR of 30 dB is required and using $W=1$ μ m, one calculates that the maximum grain size should be about 9 nm for the 2/3 rate (1,7) encoded data and 7.5 nm for the $d=0$, 8/9 rate encoded data. More accurate calculations of the expected SNR, based upon micromagnetic calculations,⁶ confirm these approximate grain size requirements.

Such small grain sizes raise the concern that thermal effects may destabilize the magnetization in the recorded transitions. Lu and Charap^{7,8} have pointed out that the demagnetizing fields in a recorded transition act in a manner to destabilize the grains and broaden the transitions. When they took the demagnetizing fields into account, they nevertheless were able to identify a region of magnetization and anisotropy in which media with a grain size of about 10 nm would

be stable. For media with a thickness of 10 nm, they found that it was necessary to have an anisotropy in excess of about 3.5×10^6 ergs/cm³ to have adequate stability.

In an accompanying paper in this session, an extensive discussion of the progress toward making media with sufficiently small grain size for adequate SNR, sufficiently high anisotropy for thermal stability and sufficiently high coercivity to achieve 10 Gbit/in.² recording density is described.⁹

V. WRITE HEADS

The requirements for high track density and high linear density place stringent requirements upon the magnetic recording heads which are used for 10 Gbit/in.² recording. The write head pole width has to be narrower than the trackpitch to allow for a narrow erase band between tracks and for track misregistration. Prior numerical modelling indicated that a write head with trackwidth of 0.6 μ m, trimmed poles and a gapwidth of 0.18 μ m would write a trackwidth which was about 0.8 μ m wide and which would have a 0.05 μ m wide erase band at both edges.¹⁰ This would allow about 0.1 μ m for track misregistration. Imperfect pole edge trimming, or more track misregistration tolerance would require either a slightly narrower gap or narrower pole.

The needs for a narrow transition parameter and for thermal stability of the magnetization require the coercivity of the media to be large. This in turn makes it necessary for the record head to be able to produce large fields. With the extremely short throat heights expected to be required for 10 Gbit/in.² recording, pole tip saturation, rather than saturation at the back gap or in the sloping region near the throat is expected to be the limiting factor for thin film write heads.

To achieve good overwrite, it is generally required that the head produce a record field at the back of the medium, which is 2.5 times the coercivity.¹¹ The field H_x produced by the record head may be estimated by calculating the Karlqvist head field¹² at the gap center and at a distance $d+\delta$ from the pole tips,

$$H_x = \frac{2H_g}{\pi} \tan^{-1} \left[\frac{g}{2(d+\delta)} \right], \quad (4)$$

where H_g is the deep gap field of the head and g is the gap length of the head. By setting $H_x=2.5 H_c$ and rearranging the equation, one can calculate the deep gap field H_g required to write on a given coercivity medium:

$$H_g = 1.25 \pi H_c / \tan^{-1} \left[\frac{g}{2(d+\delta)} \right]. \quad (5)$$

As described above, it is expected that, for 10 Gbit/in.², it will be required that $H_c=3000$ Oe, $d=20$ nm, $\delta=10$ nm, and $g=0.18$ μ m. Substituting these values into Eq. (5), one finds that the deep gap field of the head must exceed 9400 Oe to achieve good overwrite. Saturation effects generally become significant when the deep gap field is 50% to 80% of the saturation flux density.¹³ Hence, Permalloy, with a saturation flux density of 10 000 G, is not adequate for writing on such high coercivity media, even at such low flying heights.

To write at such densities on 3000 Oe media will require write head materials with larger saturation flux densities than

Permalloy. A very promising class of materials for this application is FeXN. These materials have saturation flux densities approaching 20 kG.^{14,15} Using the criterion given in Eq. (5) and that the deep gap field be no larger than 50% to 80% of the saturation flux density, these materials are expected to be able to saturate media with coercivities up to 3200–5100 Oe.

In addition to having a high saturation magnetization, these materials exhibit hardness of 19 GP (twice that of Permalloy) and resistivities of the order of 100 $\mu\Omega$ cm (about four times that of Permalloy). The higher resistivity of these materials makes them operate well to high frequencies. Single layer films exhibit a roll off in permeability at about 60 MHz, and lamination with SiO₂ or Al₂O₃ has been shown to push the roll-off frequency up to beyond 200 MHz.¹⁴

These materials have also been shown to operate well in thin film head structures. Measurements of core inductance show no roll off in the 0 to 50 MHz range,¹⁶ and in an accompanying paper in this conference, a FeAlN head with 1 μ m trackwidth and a gap length of 0.2 μ m is described.¹⁷ This head was shown to saturate media with 2950 Oe coercivity and to provide more than 40 dB overwrite at a head to medium-midplane spacing of 80 nm. With a reduced flying height, it is likely such heads could be used to achieve the linear recording densities of 12 000 to 18 000 fr/mm required for recording at 10 Gbit/in.²

VI. READ HEADS

It is expected that, to achieve an adequate signal at 10 Gbit/in.², giant magnetoresistive (GMR) read heads will be necessary. This is because the sensitivity of standard magnetoresistive (MR) heads is too low to enable media noise limited performance with the trackwidths required.

To allow for track misregistration during readout, the read trackwidth is usually made somewhat narrower than the write trackwidth. Thus, a read trackwidth on the order of 0.5 μ m might be used for 1 μ m trackpitch. Conventional MR heads have been shown to produce an output sensitivity on the order of 0.3 mV/ μ m of trackwidth² and would provide only about 150 μ V of signal, which is likely to be too low to be media noise limited. On the other hand, spin-valve read heads have been demonstrated to have outputs of 1 mV/ μ m of trackwidth¹⁸ and could produce as much as 500 μ V of output, which is expected to be adequate to enable media noise limited performance.

A challenge in fabricating 10 Gbit/in.² recording heads will be to achieve the linear resolution necessary. To obtain sufficient resolution during readout, the spin valve must be placed between two shields, the spacing between which will determine the readback resolution. To achieve the 18 000 fr/mm density ($b=56$ nm) for the $d=0$, 8/9 rate code, the shield-to-shield spacing (2g for a MR or spin-valve head) would have to be of the order of 0.1 μ m to stay well below the first gap null of the recording head which occurs approximately when $2b=g$.

A more extensive discussion of spin-valve heads for 10 Gbit/in.² recording is given in an accompanying paper in this session.¹⁹

VII. SERVOS AND ACTUATORS

Control systems consist of four fundamental parts—a dynamic system to be controlled, sensors, actuators, and a means of computation. The goal of achieving 10 Gbit/in.² with the corresponding track density of 1000 tracks/mm provides challenges in each of these areas. The problem is not only one of maintaining a sufficiently small position error during tracking (less than 10% of the track width or 0.1 μ m); it is also one of achieving sufficiently high seek performance to make random access data retrieval practical.

A. HDA dynamics

The spindle bearing contributes both repeatable and non-repeatable runout during tracking. Current methods of compensating for repeatable runout are very effective up to several harmonics of the spindle frequency, but uncompensated runout above the bandwidth of the actuator must be reduced to 0.02 μ m for a typical track misregistration budget with a 1 μ m trackpitch.

Ironically, fluid bearing spindles have been developed as components with virtually unmeasurable runout, but when used in operating prototype disk drives, nonrepeatable runout in the position error signal has not been significantly reduced. This is no doubt due to disturbance induced from aerodynamic forces from turbulent flow around the swing arm, suspension, and slider and from friction dynamics from contact or near contact of the slider with the disk surface. As disk components decrease in size, the relative importance of these forces will increase, since they scale with area. It is likely that the flow and friction dynamics will determine the required bandwidth of the servo system.

Ball bearings exhibit complex behavior for very small motions (approximately 0.001° for a single track seek at 1000 tp mm) associated with use in disk drives.²⁰ Dynamics of the rotary actuator pivot bearing affect the performance of the servo system. The hysteresis in the bias torque of the bearing can cause “hunting” or limit cycling in the seek servo, for instance. The performance of the seek servo can be dramatically improved by using an accurate prediction of the bias force to set the initial condition of the integrator of the track follow controller.²¹ Compensation for the nonlinear dynamics of the pivot bearing during tracking may also give significant performance improvements.

B. Position sensing

Determining the position of the read/write head relative to the center of the data track is an enormous challenge. An accurate position error signal (PES), which is available at a sufficiently high bandwidth and which is robust to noise, is essential for high performance servo control. State of the art PES generation using spin valve head sensors and sector servo is the most likely candidate for achieving 0.1 μ m tracking accuracy. The difficulty is providing a PES at a sufficiently high sample rate while maintaining a servo overhead less than 10% of the disk area. (A servo bandwidth of 2 kHz on a drive rotating at 6000 rpm, from a practical standpoint, would require a PES of at least 6 kHz corresponding to 60 servo sectors on a platter.) Experimental and theoretical

investigations of amplitude (split burst), phase, and null servo methods, indicate that the null servo pattern is the most robust to media and electronics noise.²²

There are several impediments to simply scaling existing servo patterns. Making reading and writing patterns difficult are the differing positive and negative pulse responses of spin valve heads and how the side-writing properties of thin film inductive heads change with size.²² Simply writing the servo patterns will take much longer because there will be more tracks. If external sensing of position is used during servo write, then the nonrepeatable runout must be very low to avoid pinch and squeeze in the data tracks. Self-servo writing may be the way to avoid these last two problems, and improvements in heads and media may alleviate the first two.

C. Actuators

The central problem of current disk drive servos is that the actuator and the sensor are not colocated. Resonances in the actuator structure between the voice coil motor (VCM) and the read/write head limit the bandwidth of the servo system. The bandwidth of the servo can be no greater than approximately 1/5 of the frequency of the lowest resonance of the actuator. Assuming that disk and spindle inertias remain constant, the amplitude of the response disturbances generally decrease with the square of the frequency of the disturbances. The 1 μm trackwidth specification is approximately a factor of 4 beyond the state of the art, so the actuator bandwidth will need to increase by a factor of 2.

While much progress has been made in improving actuators, it is unclear if the frequencies of the mechanical resonances of a single stage actuator can be increased sufficiently without reducing size dramatically. A possible solution is to dampen the first resonance so that the bandwidth of the servo can be closer to the first resonance frequency.

The problem of noncolocated actuator and sensing has led to many proposals for dual stage actuation in which a high bandwidth secondary actuator is located between the primary VCM actuator and the read/write head. While the certainty in the technical community about the need for dual stage actuation to reach the 1000 tracks/mm target has lessened, there remains a tremendous amount of interest in the idea. The two central issues in dual stage actuation are where to put the secondary actuator and what type of electromechanical energy conversion to use. Attempted solutions include putting a piezoelectric actuator on the swing arm of a rotary actuator,²³ putting an electrostatic actuator between the gimbal and slider²⁴ and putting an electromagnetic actuator between the suspension and slider.²⁵ These designs have failed to gain wide acceptance for a variety of reasons including (in selected cases) large actuator voltage requirements and lack of robustness against the shock encountered in the head-gimbal assembly.

An important issue for the use of microactuators is again servo writing. The closer the secondary actuator is located to the write head, the more difficult it is to use a laser interferometer based servo writer. The actuators would need to be locked, a self-servo-writing scheme must be used, or something akin to the Sony PERM media²⁶ which has tracks that are separated by grooves, would be necessary.

In spite of their current problems, microactuators are expected to be used in future disk drives, if not at 10 Gbit/in.², then later.

D. Computation needs

The computation needs of the algorithms for compensating for repeatable runout, time varying plant parameters, bearing dynamics, etc., place increasing demands on the digital signal processor of the disk drive. Nonlinear control is especially difficult because it may require the use of transcendental functions which must be computed on line or referenced from a lookup table. Friction models, for instance, often use exponentials, and compensation methods may use logarithms. Nor is there relief from the lower sample rates imposed by sector servo PES generation. The low sample rates for actual data mean that multirate control must be used. Beyond just the update of the control signal at 2–4 times the PES sample rate, multirate control requires open loop estimation of the plant states. Accurate plant parameters estimates needed for the state observer may necessitate the use of sophisticated adaptive identification schemes as well.

VIII. CHANNEL ELECTRONICS

There exist a wide range of tradeoffs in the design of a magnetic recording channel for 10 Gbit/in.² recording. This makes it possible to develop channel designs with widely different characteristics. The easiest way to illustrate this is to consider three extremely different cases. In the first case, heads, media, and suspension (fly height) have all achieved their goals. In this case, channel electronics will be operating at familiar linear densities—around 2.5 user bits/PW₅₀ (PW₅₀ is the width of the response to an isolated transition at half of its peak amplitude. It is a standard measure of the time resolution of the channel.)—but at lower SNRs than in today's products. Error correction codes (ECC), detection and equalization algorithms would be extensions of those used today but designed for operation at lower SNRs.

In the second case, the PW₅₀ achieved is significantly larger than that needed to achieve 10 Gbit/in.² at only 2.5 bits/PW₅₀. In this case, 10 Gbit/in.² may still be achievable by using more sophisticated signal processing algorithms designed to operate at 3.0 user bits/PW₅₀ or even higher linear densities. However, the SNR required to achieve an acceptable overall error rate before ECC is applied (on the order of 10⁻⁴ or 10⁻⁵ raw bit error rate) will be higher at higher user bit densities. In this case, the constraints on media noise and electronics noise (head noise+preamp noise) will be tighter, but the constraint on PW₅₀ will be relaxed. It is this tradeoff between the performance requirements on the head, media, and fly height that can be facilitated by changing the channel electronics.

In the third case, the PW₅₀ of an isolated pulse is acceptable, but when transitions are written at the spacing necessary to support a density of 10 Gbit/in.², a supra-linear decrease in the SNR occurs. Typically, this is a result of the zig-zag domain walls of one transition approaching or even merging with those of an adjacent transition.²⁷ A density of 10 Gbit/in.² could still be achieved by using a run-length-

limited (RLL) code in which adjacent transitions are prohibited [e.g., the 2/3(1,7) RLL code frequently used with peak detection channels]. For the 2/3(1,7) code, we must read and write "symbols" at 1.5 times the desired bit rate, but flux reversals will never occur in adjacent symbol cells. Therefore, flux reversals are 1.33 times further apart than they would be on an uncoded channel at the same density. Note, for reasons of clock recovery alone all channels use some form of RLL code; hence, they suffer some rate loss. Currently, $d=0$ codes with a rate of 8/9 are common and ones with a rate of 15/16 are being used in research. Again, the use of an RLL code with $d>0$ results in a loss in SNR if the channel itself was purely linear. However, when the channel exhibits a supra-linear decrease in SNR with increasing flux reversal density a $d>0$ coded channel may offer improved performance. Note, one serious implementation penalty which must be addressed in this scenario is that the channel clock must operate roughly 33% faster than that of a $d=0$ rate 8/9 channel.

Advanced channels for 10 Gbit/in.² density are expected to utilize "sampling" detectors which make their decisions based on a sequence of samples of the equalized readback signal taken at the symbol rate. They fall into two broad approaches. The first approach employs nonideal equalization (i.e., equalization that decreases the detection SNR of the signal) followed by an ideal detector. The pulse response (two opposite going transitions at adjacent symbol times) of the channel plus equalizer is adjusted to match that of a simple partial response (PR) polynomial; e.g., PR4 is (1,0,-1) and EPR4 is (1,1,-1,-1).²⁸ The better the spectrum of the selected PR polynomial matches that of the original channel, the less the SNR is degraded. Detection is performed by the optimal (provably so in the presence of only additive Gaussian white noise, assumed so in all other cases) detector,²⁹ a maximum likelihood (ML) detector implemented recursively using the Viterbi Algorithm.³⁰

The second approach employs equalization of the channel as well, but in this case the equalizer does not degrade the SNR of the channel. Its job is only to "sharpen" the leading edge of the pulse response so that "precursor" intersymbol interference (ISI) is suppressed. Note, in a magnetic recording channel, the read head senses the magnetic field from a transition even before it arrives over the transition. Because the trailing edge of the equalized pulse response is relatively unconstrained (we do try to limit the total energy in the trailing ISI) it is always possible to shape the frequency response of the equalizing filter so that the SNR is not degraded. Typically the number of nonzero symbols (i.e., the "extent") of the pulse response of this type of equalizer is significantly longer than the extent of the above PR responses. Therefore, it is impractical to use the Viterbi algorithm as a detector in this case. (Its complexity grows exponentially with the pulse response extent.) However, the general class of feedback detectors can be used. The simplest feedback detector is the Decision Feedback Equalizer (DFE).³¹ In this case the detector's own decisions are used to subtract the trailing ISI. Assuming these decisions are correct and an accurate model of the channel pulse response is used, trailing ISI can be completely removed. The nonideality of

this approach is that there is energy which could help in making the decisions in the trailing ISI and the DFE subtracts off that energy. This can be mitigated by taking several terms of the pulse response into account in a fixed-delay tree search (FDTS) detector in place of the DFE slicer resulting in an FDTS/DF detector.³²

The relative SNR of several of these signal processing algorithms as a function of user bits/PW₅₀ for RLL codes with $d=0$, $d=1$, and $d=2$ are compared in Ref. 32. Based on the comparisons, sequence detectors in general perform much better than traditional peak detectors, especially at high density. In addition, the most common sequence detector, PR4-ML, is seen to be somewhat poorer in performance relative to other sequence detection algorithms as user densities approach 3 bits/PW₅₀. And, when $d>0$, FDTS/DF detectors outperform nearly all other sequence detectors as density approaches 3 user bits/PW₅₀.

An issue which cannot be neglected when selecting a channel equalization and detection algorithm is the implementation complexity of the overall design. This problem has grown acute in recent years because more sophisticated signal processing algorithms are being implemented at increasingly fast clock rates. Clock rates have increased dramatically because (1) disk rotation speeds continue to increase (10 000 rpm will be common by the year 2000), (2) the recent rapid increase in linear density of magnetic recording channels based on the use of magneto-resistive heads, and (3) a relatively slow decrease in disk diameters.³³ For example, the user bit rate at the outer diameter of a 3.5" disk, assuming a linear density of 400 Kbp/in. and a rotation rate of 10 000 rpm, is 733 Mb/s. The IC designer is further challenged by power consumption limitations set by battery life issues in portable applications and by power dissipation limits of inexpensive plastic packages in desktop applications. Die area must be kept to a minimum in order to decrease cost. These constraints demand new innovative approaches to channel design. For example, one alternative is to implement signal processing using high speed analog electronics circuits for equalization and detection.³⁴

IX. CONCLUSIONS

It is expected that, shortly after year 2000, commercial disk drives will achieve a storage density of 10 Gbit/in.² It is believed this level of performance will be achieved with flying heads on longitudinal, high coercivity, fine grain, magnetic media. The heads will likely use high magnetization (>13 kG) materials for recording and spin valves for read-out. Although some form of micro-actuator technology is eventually expected, it may not be necessary in order to achieve 10 Gbit/in.² recording if a robust sector servo pattern such as the null pattern is used for the PES. If the channel is approximately linear, $d=0$ codes and some form of partial response detector are expected to be used; however, if the channel exhibits a supra-linear noise increase at the PW₅₀ required to support 10 Gbit/in.² density, a $d>0$ coded channel with a FDTS/DF detector may be preferred.

Advances in magnetoresistive materials have recently enabled magnetic recording heads to achieve higher levels of performance. This article describes why higher signal outputs are necessary for improvements to be made in areal density. The requirements for recording at an areal density of 16 Mb/mm² (10 Gb/in.²) are discussed with regards to both the channel and the head design. Increased output from new multilayer magnetoresistive materials is required to counteract the decrease in output due to the reduction in the size of the head geometry. An areal density of 16 Mb/mm² is shown to be feasible with spin valve recording heads using materials with magnetoresistance ratios of 10%. Fabrication issues relating to the manufacturing of these materials are shown to be more stringent than previously required. © 1996 American Institute of Physics.

I. INTRODUCTION

Magnetoresistive recording heads have only recently been introduced into the magnetic recording industry but they have heralded a new interest in the basic properties of magnetic materials. What is driving this interest is the direct link between the magnitude of the magnetoresistance of the sensor material and the final storage capacity of the disk drive. With the storage requirements for applications increasing rapidly it is not surprising that there has been a keen interest in pushing materials to larger magnetoresistance. New multilayer films, for example the giant magnetoresistive materials,¹ are being developed with a variety of properties that can be tailored to meet the needs of the new technology. Other novel sensors have been proposed, for instance tunneling devices which depend on the tunneling of electrons from one magnetic layer to another,² and colossal magnetoresistive materials³ which have a structure similar to high T_c superconductors. With the phenomenon of electron transport at small length scales becoming better understood it is well within possibility that a "magnetic switch" is only just around the corner.

This article will describe the reasons why higher magnetoresistance is needed in order to achieve areal densities of 16 Mb/mm² (10 Gb/in.²). Section II will show how the drive electronics set the requirements for the signal-to-noise ratio (SNR), and that the SNR is dependent on both the head and the media. Geometrical constraints conspire to reduce the output of the head and some of the design principles will be discussed. Multilayer giant magnetoresistive (GMR) recording heads are one direction that industry is pursuing to take advantage of higher magnetoresistance effects, and some of the fabrication issues will be described in Sec. III. Finally, we will indicate some future directions for magnetic materials that appear promising in the pursuit of even higher areal densities.

II. OUTPUT REQUIREMENTS FOR 16 Mb/mm²

An example of a typical magnetoresistive (MR) head geometry that could be used to achieve 16 Mb/mm² is shown in Fig. 1. Sandwiched between shields is a magnetoresistive element with two conductors that make contact with the MR element. A sense current is used to measure the change in resistance of the element as a recorded bit in the media passes underneath the head. The bits are written by fringing fields that jump the gap between the write pole and the shield when current is applied to the write coils.

The read width ℓ in this particular head geometry is defined by the region of the element that is sensed by the two contacts. The distance between the shields, called the gap length g , controls the resolution of the sensor along the track. The distance from the bottom of the sensor to the top of the magnetic layer in the media is defined as the magnetic spacing, d .

There is a trade-off between the read width and the gap length in order to reach the areal density goal of 16 Mb/mm². A number of different cases have been considered by Murdock, Simmons, and Davidson⁴ in an article outlining the trends in media for achieving 16 Mb/mm². As an example that is equally aggressive in both dimensions, we will use a

FIG. 1. Geometry of a dual gap MR recording head. The top shield of the read element also serves as the bottom pole of the write element.

FIG. 2. (a) The error rate of a recording channel at 16 Mb/mm² as a function of head output. The media noise is indicated as a SNR where all electronics noise is subtracted and only the media noise contributes to the dB figure (channel density=2.5 bits/Pw50). (b) The error rate as a function of head output for an areal density corresponding to current products (1.6 b/mm²: 6.8 kb/mm, 275 b/mm) and at 16 Mb/mm (16 kb/mm, 1000 tr/mm).

design point of 1000 recorded tracks/mm and 16 000 bits/mm along the track for a total of 16 Mb/mm² [case three in Ref. 4]. This results in the width of the track being 1 μm and the length of each bit being 63 nm.

A. Head SNR

An increase in the linear density from the present day 5000 bits/mm to 16 000 bits/mm requires that the head produce more signal in order to maintain an adequate signal-to-noise ratio. To understand the demands that this places on the head output we will use a model of a recording channel to show how an increase in signal leads to an increase in the ability to achieve higher areal densities.

The usual starting point is from the error rate. Although error correction codes are continually being improved, in the time frame for products at 16 Mb/mm² the error rate should probably not exceed one error in 10⁵. This error rate will determine the output signal that will be required from the recording head. A standard PR4 partial response channel with Viterbi detection was used.⁵ The input to the model was an isolated pulse that was measured for a MR head with present day recording heads and media. This pulse was scaled to higher outputs and narrower pulse widths to simulate recording at the higher density. The data rate determines the overall bandwidth of the system and this was set at an aggressive 325 Mbits/s (e.g., reading 16 000 bits/mm at the outer diameter of a 1.3 in. hard disk spinning at 12 000 rpm).

An important parameter for any channel is the amount of noise. Three sources of noise were assumed: the noise from the media, the Johnson noise of the magnetoresistive sensor, and the preamp noise. Media noise is the most important and was determined by linearly extrapolating the measured noise of currently available media. The amount of noise was scaled to simulate better media yet to be developed, and was also extrapolated to narrower tracks by assuming that the noise will vary as the square root of the track width (track edge noise was not included). Johnson noise was for a head with 25 Ω of resistance and the preamp noise was 0.5 nV/ $\sqrt{\text{Hz}}$. The final bit error rate for the PR4 channel as a function of head output is shown in Fig. 2.

Figure 2(a) shows that the final error rate is determined both by the head output and by the media noise properties. So long as the system is not media noise dominated an increase in output will give a better SNR and hence a better error rate. If media noise is dominant, the head senses the media noise in the same manner as it does the recorded transitions and an increase in signal does not improve the SNR.

Examples of typical head outputs are obtained from Fig. 2(a). For example, if the media has very low noise, 25 dB, the required output of the head is only 1 mV/ μm . More realistically, given the difficulties of developing low noise media, a media with 22 dB of noise will require a head output of 1.5 mV/ μm . As a spur to media development, Fig. 2(a) also indicates that with present day media at 19 dB we will never reach 16 Mb/mm² regardless of the output of the head.

The model was used to determine the output at 1.6 Mb/mm² using parameters representative of today's products (1.8 bits/Pw50, 190 Mb/s). This is compared with data for 16 Mb/mm² in Fig. 2(b). The SNR for the media at the lower density was also 25 dB (it should be noted 25 dB media at 1.6 Mb/mm² and 25 dB media at 16 Mb/mm² are not the same media since the SNR is measured at each density). The SNR requirement of the channel drives the need for more signal from the head. Whereas today's products only need 100 $\mu\text{V}/\mu\text{m}$ from the recording head, products at 16 Mb/mm² will need a factor of 10 greater output to compensate for the lower signal from the narrower track and the higher bandwidth.

B. Head geometry

The reduced read width at higher track densities will, in general, result in less output. Providing other parameters are kept constant, the signal will decrease proportionally with the read width. It might be argued that the output can be kept the same merely by going to narrower MR heights in order to keep the resistance constant. Unfortunately, power dissipation also needs to be taken into consideration. With a smaller MR height the current needs to be decreased to keep the power dissipated per unit area the same and, as a result, the output signal will be reduced. This is somewhat mitigated by the ability of smaller geometries to dissipate heat more efficiently⁶ but, in general, to maintain a constant SNR the magnetoresistance of the device will need to be increased to compensate for the decreased read width.

An additional effect that reduces the output is due to the decrease in response at the edge of the defined read area. A number of factors may contribute to this effect, for instance the current distribution at the edge of the track may not be sufficiently sharp or the magnetic material in the active region may interact with the magnetic material outside the region.⁷ Since the track edge effects become a proportionally larger part of the total signal as the track width decreases, these effects will also make it necessary to increase the head output.⁸

The output of the recording head will, in general, depend strongly on the gap length. With a shorter gap length there is effectively a smaller aperture exposed to the flux from the media and, in addition, the flux will decay into the shield

FIG. 3. (a) Variation in output for a dual-stripe head as a function of the MR height (track width = $0.5 \mu\text{m}$, gap = $0.13 \mu\text{m}$, $dR/R = 2.5\%$, $Mr\delta = 0.5 \text{ m emu/cm}^2$, flying height = 25 nm). (b) Output of a spin valve head as a function of element height for different current densities (parameters same as for (a) except gap = 0.15 and $dR/R = 10\%$). The media was included in the models using a Green's function method (Ref. 9).

more quickly, resulting in a lower head efficiency. This loss of efficiency can be countered by either designing the head to fly closer to the media to minimize the effect of a smaller aperture, or by reducing the MR height to reduce the loss to the shields. While in both cases signal can be regained, there may be practical limitations on the ability to either fly lower or fabricate narrower MR heights, leading to the need for greater magnetoresistance to regain signal.

Reducing the MR element height to regain efficiency makes a conventional MR head more difficult to bias. This purely magnetic effect arises from the demagnetizing fields present in the MR element which become stronger as the element is reduced in height. In principle, these fields could be reduced by going to thinner MR films. However, in a conventional MR head a certain current density is required in order to bias the head into a region where the output is linear. An example is shown in Fig. 3(a) where the output of a dual-stripe head was calculated at 16 Mb/mm^2 using a model similar to Smith's 2D micromagnetic model.⁹ For a given current density there is an optimum MR height where the maximum output is obtained. Below this optimum the output will drop drastically. Higher currents permit narrower heights to be used, but this increases the resistance and the power dissipation becomes prohibitive.

C. Parameter trade-offs

The need for higher signal level is also driven by the fact that other parameters are becoming ever harder to improve. For instance, the pulse width is a function of both the flying height and the gap length. This is described by the equation¹⁰

$$\text{Pw50} \cong \sqrt{[g^2/2 + 4(a+d)^2]}, \quad (1)$$

where g and d are defined above and a is the transition length in the media. Assuming 16 kb/mm and 2.5 bits/Pw50 gives the pulse width $\text{Pw50} = 0.16 \mu\text{m}$. Assuming improvements in tribology will lead to magnetic spacings of roughly 30 nm leads to the required gap length for 16 Mb/mm^2 being $0.16 \mu\text{m}$. As was seen above, if the output of the head is sufficiently large to be able to use a narrower gap and still achieve the same SNR, then a higher flying height would still give the same Pw50. Improvements in the magnetoresistance

would lead to a relaxation of the magnetic spacing requirement allowing perhaps a thicker wear layer and better robustness of the disk drive.

A similar trade-off was illustrated above in Fig. 2(a), where a higher signal would allow media with poorer noise properties to be used to achieve the same areal density. Basically, a certain level of performance is required from the head; however, if additional signal were possible this would allow other tolerances to be relaxed.

III. GIANT MAGNETORESISTIVE HEADS

A. Head design

Giant magnetoresistive materials have recently been developed¹¹ and the most promising candidates for a read head with the output necessary to achieve 16 Mb/mm^2 are spin valve devices¹² (alternate designs for GMR heads have recently been proposed by Rottmayer *et al.*¹³ and Smith *et al.*¹⁴ but they will not be described here).

Conventional magnetoresistance materials (permalloy) have magnetoresistance ratios of 2.5%; single spin valves, 10%; and dual spin valves up to 23%.¹⁵ Films at the higher percent ranges tend to have more coercivity than desirable for devices,¹⁶ so typical spin valve recording heads have magnetoresistive ratios of $\sim 10\%$, a factor of 4 greater than that of permalloy.

A spin valve head utilizes a magnetoresistive element that is composed of two magnetic layers separated by a conducting but nonmagnetic spacer. One film serves as the sense film with the magnetization along the length of the element. Separated from it by a thin metallic layer, usually Cu, is another magnetic layer with a magnetization that is oriented transverse to the length of the element. The magnetization of this film is typically pinned by an antiferromagnet. The field from the media rotates the magnetization in the sense layer, and changes the relative angle of the magnetizations in the two magnetic layers. The resistance of the device scales as the cosine of this angle.¹² The design of the structure requires a careful balancing of magnetic fields present in the device: the demagnetizing fields of individual magnetic layers, the fields from the sense current, internal anisotropy fields, and fields that arise from coupling between the layers. This latter field is of special importance as it depends strongly on the thickness of the Cu layer.¹⁷ Micromagnetic models have recently been published outlining this optimization.¹⁸

A major feature of the spin valve device that makes it useful for 16 Mb/mm^2 recording is that it remains biased even as the MR element height is reduced. This is because the magnetization of the sense film remains along the element length resulting in the output of the device being linear about zero field. An AMR head requires that the magnetization be oriented at an angle relative to the sense current and this becomes harder to achieve for smaller geometries where demagnetizing fields become important. To illustrate the effect of bias a spin valve head was modeled at 16 Mb/mm^2 using 2D micromagnetics, shown in Fig. 3(b), and it is seen that the head output monotonically increases as the MR height is reduced. In contrast, the dual-stripe head output shown in Fig. 3(a) decreases below a certain MR height be-

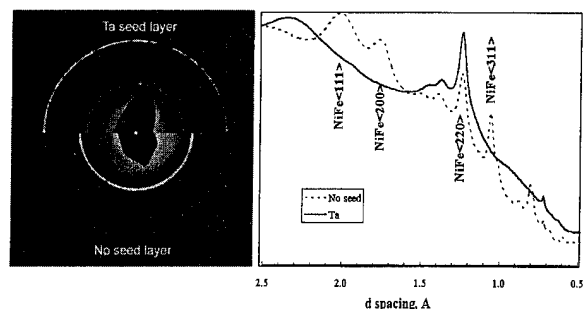

FIG. 4. Illustration of the effect of a Ta and a Cr underlayer on the crystallographic texture of 10 nm thick NiFe.

cause of the increasing difficulty in maintaining the proper orientation of the magnetization. With a magnetoresistance ratio of 10% the output of the spin valve head can easily achieve 1–2 mV p - $p/\mu\text{m}$, a value that was shown above to be adequate for 16 Mb/mm² recording. Outputs in this range have recently been demonstrated by IBM and Hitachi for spin valve heads.¹⁹

B. Fabrication challenges

The giant magnetoresistance effect requires that the films be very thin. For instance, the total thickness of the conducting layers must be within the mean free path of the electron, about 10 nm, otherwise the effect is reduced. This is an advantage because the gap length decreases at higher recording densities and a thin sensor allows a thicker dielectric to be used as the insulator in the gap. In addition, the trend for media at higher density is to become thinner⁴ and to remain matched to the media the sense layer must also be reduced in thickness. A typical spin valve will have a 5–10 nm thick magnetic sense layer, a 2–3 nm spacer layer of copper, and a 2–5 nm pinned magnetic layer. The pinning is achieved by using an antiferromagnetic film such as FeMn or NiO. The magnetic layers will typically be of NiFe and Co; the Co is used to increase the GMR effect and improve the stability of the interface and the NiFe is used to increase the sensitivity of the sense layer.

Fabricating multilayers with individual films in this thickness range for a commercial product will be a challenge not only from the standpoint of thickness control, but also because of the need to control the film structure. For instance, the crystallographic structure of giant magnetoresistive films is very important in determining the magnetic and the transport properties of the materials. Grain boundaries cause the electrons to be scattered and this results in a decrease in the magnetoresistance. Additionally, it has been shown that the orientation of the films is important in determining the coupling strength between the ferromagnetic film and the antiferromagnetic film that is used to pin the magnetization.²⁰

The crystallographic texture of the film can be controlled by using underlayers. This is illustrated in Fig. 4, where a plan-view TEM diffraction pattern is used to determine the orientation of NiFe deposited with and without an underlayer. Without any underlayer diffraction was from (111), (200), (220), and (311) planes, suggesting a randomly ori-

FIG. 5. Cross-sectional TEM micrograph of a sputtered Ti/Co/Cu/Co/FeMn spin valve structure.

ented polycrystalline film. In contrast, a Ta layer produces a NiFe film that is strongly (111) textured, as evidenced by the presence of only the (220) diffraction ring.

The ability of one layer to control the orientation of subsequently deposited layers has serious consequences for structures that are composed of many different layers. Fortunately, cross-sectional TEM opens up a window on the microstructure of the thin films used in giant magnetoresistive heads. In Fig. 5 is shown a TEM cross section of a GMR spin valve that uses Ti as an underlayer to control the orientation.

The structure shows good epitaxy between layers. This translates into superior transport properties over films that show poor epitaxy. Relating the structure of the films and their interfaces to transport properties is presently one of the main challenges that are being faced by groups working on the optimization of GMR structures. Theoretical models for transport properties are becoming more refined and serve to guide experimentalists in the design of the multilayer materials.²¹

IV. FUTURE DIRECTIONS

Even more exciting is the potential for materials that behave like magnetic switches. Figure 6 shows the change in resistance of the perovskite $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ grown by metal-organic chemical-vapor deposition (MOCVD). At room temperature the change in resistance is 94% (defined as $\Delta R/R_{\text{max}}$). However, the field required is 5 T, much too high for application as a sensor, but these materials are only beginning to be understood and many research groups have taken on the task of reducing the saturation field. As above, the epitaxial growth of the materials is important but, in addition, the stoichiometry and postprocessing of these films has also been found to be important for achieving high magnetoresistance.

The drive electronics for a material of this type would probably not be of the same type as for a conventional head. The sensor would switch from a relatively low resistance, perhaps 10 Ω to a very large resistance on the order of k Ω or

FIG. 6. Resistivity and magnetoresistive signal of the perovskite $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$.

even $\text{M}\Omega$. The resistive noise would be determined not by the head, but rather by other resistances in the input circuitry. For cases where the magnetoresistance change approaches 100% the SNR of the head could be extremely large, leading the way to areal densities much higher than 16 Mb/mm^2 .

Tunnel junctions composed of two magnetic materials separated by a dielectric have also shown promise recently. Miyazaki and Tezuka² have demonstrated magnetoresistive effects of 18% at room temperature in low fields. The entire subject of magnetotransport in heterostructures is only in its infancy.²² However, the careful tuning of material properties to achieve the required electrical and magnetic properties is proving to have a large impact on the recording industry.

V. SUMMARY

Future increases in areal density and data rate require that the output of the read head become larger. This has been shown to arise from the need to maintain a constant SNR while contributions from noise sources increase. The decrease in gap length, element height, and read width all conspire to reduce the head output, necessitating a gain in the signal by improving the magnetoresistive ratio of the material. New spin valve devices promise to provide a factor of 10 improvement in magnetoresistance over conventional materials and on the horizon are even newer materials that promise even greater magnetoresistance. However, careful control over structural properties will be required because the films are so thin and because they rely on subtle effects in magnetotransport. The theoretical understanding of new types of magnetoresistive materials is making rapid progress and it would not be surprising if a low-field "magnetic switch" were soon to be developed.

ACKNOWLEDGMENTS

The authors would like to thank the members of the National Storage Industry Consortium's project on Ultrahigh Density Recording Heads for many stimulating discussions regarding high-density recording. They also would like to thank Dick Baugh for use of his channel model, Pascale Bayle and Amanda Petford-Long of Oxford for the cross-sectional TEM pictures, Jeff Rosner at HPL for the plan-view TEM picture and analysis, and Ron Hiskes of HPL and Michael Hundley of Los Alamos for the CMR data.

Future 10 Gb/in.² recording densities represent submicron trackwidths and sub-100 nm bit lengths. This requires extremely small magnetic switching units and very high coercivities of the media to satisfy the signal-to-noise ratio requirements. At the same time the question of magnetic thermal stability and the lack of transducers capable of performing at these densities makes it difficult to evaluate media. An uncoupled, highly uniform magnetic grain size of about 10 nm is a compromise toward maintaining an adequately low media noise and yet maintaining magnetic stability. Here we discuss current media construction, the detrimental role of substrate roughness, the role of new media structures and alloys on microstructure and magnetic properties as well as techniques for evaluating media performance prior to the availability of the required playback heads. © 1996 American Institute of Physics. [S0021-8979(96)39908-9]

I. INTRODUCTION

The introduction of sputtered thin-film media, onto electrolessly plated NiP on an Al substrate, has lead to a substantially smoother surface enabling record and playback heads to become closer to the medium—the single most important characteristic in magnetic recording. These advances have recently lead to an approximate 60% compound annual growth rate for areal densities¹ plus three demonstrations of areal densities in the Gb/in.² range.²⁻⁴ The technology which is commercially available today incorporates 0.4–0.8 Gb/in.² areal densities and is on the 60% growth curve.

In 1992, Murdock *et al.*⁵ described several possible recording formats and outlined the required mechanical, magnetic, and recording performance requirements to achieve 10 Gb/in.² areal densities. The selection and matching of the head and media components as well as the tracking and signal processing techniques is currently a complex iteration process and the evaluation of each of these individual components is hampered by the lack of the other. Here, we review and describe some of the hard disk media issues and a philosophy for developing future media when advanced recording and playback heads are not available. By example, we will try to put into perspective where media technology is today and what limits its performance.

II. RECORDING FORMAT AND MAGNETIC REQUIREMENTS

Over a period of several years disk drives have maintained a fairly constant recording trackwidth to linear bit density ratio. Hence, scaling the current areal density to a 10 Gb/in.² system yields a format entirely consistent with Murdock *et al.*'s projections. One format would call for 25 400 tpi (0.5 μ m read head width) and a linear density of 400 000 bpi. A 4/3's rate code would then dictate a 300 Kfci linear density.

It is assumed that high moment inductive heads will be available for recording while spin valve head⁶ technology will be available for playback. The playback head dynamic range and head-medium spacing, then determines the desired moment of the medium. Scaling arguments⁵ indicate that for a 30–40 nm head to the center of medium spacing, a $M_r\delta=0.4$ to 0.6 memu/sq cm is needed to optimize head response while preventing head saturation nonlinearities dur-

ing playback. From a medium noise view point, it turns out to be especially advantageous to lower the recording head to medium spacing. Fortunately, the low $M_r\delta$, that spin valve head technology requires, minimizes the transition demagnetization effects to allow higher linear bit densities. As a rule of thumb the flux reversal spacing is limited to approximately πa_x .⁷ Hence, to achieve 300 Kfci density, one requires that $a_x < 27$ nm. The coercivity of the medium should approach 3000 Oe while δ should be less than 15 nm.

As usual it is anticipated⁶ that the medium noise will slightly dominate the head noise and so an isolated signal pulse to broad band media noise of 27–30 dB is required for 10 Gb/in.² (Ref. 5). Fortunately, we have the experience of particulate recording media as a guide in understanding the media noise issues. Baugh *et al.* and Belk *et al.*^{8,9} showed that media noise, measured in the frequency domain, is the smallest when the magnetic regions are composed of small, well-isolated, magnetic particles. For particulate media they found that the noise power was nearly a constant, as a function of transition density, and the smallest at high recording densities. For thin-film media, the noise power increases linearly with increasing transition density and then increases supra linearly.

The magnetic playback head samples a finite volume of the medium determined by the head field distribution. Hence, when a particulate medium is dc erased, the particles are magnetized, largely, all in one direction and fluctuations in the magnetization sensed by the head are due to either non-uniformities in the density of particles or in the random orientation of their magnetic axes. These statistically independent fluctuations yield a Gaussian probability distribution. This gives a noise power proportional to the number of particles, while the signal power is proportional to the square of the number. Hence, the lowest particulate medium noise results when the particles are small so that the number of particles sensed by the head field is maximized and when the size and orientation distribution of the particles is uniform. For the Baugh type of plot, the lowest noise is observed when the medium is in the ac-erased state as the magnetization of individual particles orient to a flux closure condition which minimizes the external fields that the head senses.

Thin film media are usually composed of closely packed, randomly oriented grains which are either magnetically

FIG. 1. Effect of record head field gradient on medium noise power for a commercially available CoCrTa hard disk.

exchange-coupled at the grain boundary, grouped as exchange-coupled clusters of grains, or, at best, grains which are somewhat isolated by nonmagnetic material. The latter behaves as particulate media, while the former behaves as large regions of continuous magnetization. For the former, the dc-erased state is the lowest noise situation as the media can be viewed as one large domain with no flux leakage from the media surface. However, at a flux reversal, the fluctuation amplitude manifests as large medium noise. Hence, a medium in which the grains are exchange-coupled exhibits a noise power that is associated with the transition and the noise power increases linearly with the transition density until the transitions are so closely spaced that they begin to interact¹⁰ and the noise power increases supra-linearly. Practically, for a medium noise limited system, the flux spacing, πa_x , is usually set to be at or slightly beyond the onset of this supra-linear regime. Therefore the following three simultaneous conditions are desired in a Baugh plot: (1) Small isolated magnetic units to give a low slope in the linear regime. (2) Small, uniform, uncoupled grains to give a low dc noise. (3) A recording transition density chosen to occur prior to the onset of the supra-linear regime.

It should be pointed out that the transition fluctuation amplitude is largely determined by the dispersion in the media characteristics (uniformly of grain size, orientation, exchange coupling, stress, etc.) and these fluctuations are exacerbated by a poor record head field gradient. That is, if the head field gradient is poor, then both a_x (Ref. 7) and the fluctuation (noise) of the transition location will be large.^{10,11} Figure 1 shows two non-normalized recording results, on the same medium, where the record head field gradient has been varied. The lower-noise curve B was obtained using a 5- μm -wide Read Rite Tripad head with a 0.22 μm gap and flying at approximately 25 nm (at 7.1 m/s velocity) while the higher-noise curve A was generated using a 6- μm -wide Quantum Diamond head with a 0.33 μm gap and flying at approximately 100 nm. Note that, not only does the supra-linear noise regime begin earlier, but the slope of the linear noise regime is larger for the recordings with the poor record field gradient. Obviously it is difficult to evaluate medium noise without the ideal head and fly height, since medium noise depends upon the head field gradient. The practical ap-

FIG. 2. Medium noise power vs linear density for CoCrTa, CoCrPt, SmCo, and CoCrPt hard disks. The data was normalized by the power in the isolated pulse signal.

proach, then, is to use a head with the smallest available gap and to fly it as low as possible. The measured medium noise will then be an upper bound. Since the noise power is mostly contained in the low-frequency spectrum,^{9,11,12} the playback system does not need to perform to the same linear densities as the recording test system. In brief, we see that the medium grains must be small, magnetically isolated, and of uniform size to minimize the noise, the film moment must be chosen to maximize the spin valve response without overdriving it, the coercivity must be high enough to prevent demagnetization, and the medium structure must be extremely smooth to allow low fly heights both to write low noise transitions and to resolve the playback pulses.

For single-domain Stoner-Wohlfarth particles, the coercivity is determined by both orientation and crystalline anisotropy energy. Also, as the grain size is reduced and the thermal energy fluctuations threaten the stability of the recorded bit it is important to maximize the magnetic crystalline anisotropy. Charap and Lu's¹³ modeling indicated that for 400 Kfci recording and cobalt parameters ($K_u=4 \times 10^6$ erg/cc, $M_s=900$ emu/cc), a grain size below 8 nm would tend to be thermally unstable. A 10 Gb/in.² medium should then have magnetic units in the 10–12 nm diameter range. The quest then is to achieve isolated grains of this size while maximizing the anisotropy. An approach to achieving high anisotropy is to build grains of such crystalline perfection that the magnetocrystalline anisotropy is maximized. The alignment of the anisotropy axis along the record track direction will also help to maximize the coercivity. However, there is modeling evidence that this type of orientation may increase medium noise.¹⁴

III. STATUS OF CURRENT MEDIA DEVELOPMENT

Figure 2 provides a comparison of the normalized medium noise power for a number of media designed for various recording densities. Table I lists the magnetic properties of each of these media. An all ones pattern was recorded on each of these media using a Read Rite Tripad head with the head to medium velocity (7.1 m/s) adjusted such that the head was flying just beyond contact of the disk. The medium

TABLE I. Magnetic properties and surface roughness details of high coercivity hard disks.

Media		Magnetic properties		Substrate			Overlayer thickness (nm)
Type	material	H_c (Oe)	$M_r t$ (memu/cm ²)	Material	State	Roughness R_{rms} (nm)	
A	CoCrTa	1900	2.1	NiP/Al	Textured	8.7	15(C)
B	CoCrTa	2200	1.0	NiP/Al	Textured	5.0	15(C)
C	CoSm	3000	0.6	Glass	Smooth	1.3	7(Cr) 10(C)
D	CoCrPt	3000	0.55	NiP/Al	Super Smooth	0.4	5(C)

noise power was obtained using the technique described earlier.^{8,9,12} Medium A (CoCrTa) was removed from a modern commercial drive operating at 0.4 Gb/in.² density. In Fig. 2, one can observe the supra-linear noise regime beginning at approximately 50 Kfci. Medium B (CoCrPt) is a commercially emerging medium designed for approximately 1–1.2 Gb/in.² density. We observe a lower slope and the supra-linear behavior at 125–150 Kfci indicating a superior medium. Sample C is a SmCo medium^{12,15} with a grain size of about 20 nm, while sample D is a CoCrPt medium with a grain size of approximately 15–20 nm. Using this close flying head neither of these latter two media appear to possess a supra-linear noise regime when recorded up to 300 Kfci. However, the linear regime's nonzero slope indicates that these media are still transition noise limited and have exchange coupling. Eventually, at higher densities the supra-linear noise behavior should be observed. A gap null occurs at 230 Kfci. A significantly sharper head field gradient should decrease the transition noise for these media provided the inherent transition noise is limited by the head field gradient and not by the media microstructure.

While a signal-to-noise ratio could be obtained by extrapolating out to 300 Kfci, MFM images can provide more accurate information plus insight into the microstructural

properties. Figures 3–5 show MFM images of transition patterns at different densities for three of the four media of Fig. 2. Clearly, just as was shown in the noise power curve, the onset of the exchange coupled transition-transition interaction has occurred for the CoCrTa medium well prior to the 150 Kfci density, Figs. 3(a)–3(c). An atomic force microscope (AFM) image, Fig. 3(d), shows the film's roughness and grain clustering due to the mechanical texturing of the substrate. Close examination of the large magnetic switching units observed in the dc-erased areas of the MFM images correlate to the AFM observed grain clusters. To avoid this noise source, future media should be prepared using smooth substrates having a smooth data zone surface.¹⁶

Experimental media C and D were prepared on a smooth glass substrate and a supersmooth NiP-Al substrate, respectively. The MFM images of these disks [Figs. 4(a)–4(c) and Figs. 5(a)–5(c), respectively] show well-resolved transitions into the 200 and the 250 Kfci regimes, respectively. The smaller magnetic unit size correlates to the substrate quality shown in Figs. 4(d) and 5(d). Other MFM features worth noting are the quiet dc-erased backgrounds, as well as, the small substrate scratch in the center of the 250 Kfci track in medium D. Even though the magnetic switching unit size of this latter medium is largely determined by the underlayer microstructure, the roughness of the scratch dominates the

transition location. Transitions at 300 Kfc were clearly visible for medium D, but Fig. 5(c) indicates that the medium SNR is unacceptable for a $0.5\ \mu\text{m}$ trackwidth.^{6,17}

IV. CURRENT MEDIA STRUCTURE APPROACH

Modern commercial media are prepared by sputter deposition and consist of a structure of a lubricant, a carbon overcoat, a magnetic layer, and a Cr underlayer, on a substrate. The carbon overcoat and the lubricant are used to provide mechanical and chemical protection to the underlying metals. Daval and Randet¹⁸ showed that an underlayer of Cr could significantly improve the magnetic properties of a Co alloy thin film. Since then, much work has been published on how the Cr underlayer influences the Co alloy microstructure and magnetic properties. The medium's coercivity and noise performance are largely determined by the Co alloy composition, grain size, and crystal orientation, perfection, and isolation. The underlayer largely effects the latter of these via promoting epitaxial growth onto the Cr crystallites. Likewise, the substrate surface strongly influences the Cr growth via both surface bonding energy¹⁹ and roughness.

In brief, depending upon the growth conditions^{19–21} the bcc Cr tends to develop with a variety of crystallographic textures. The closest packed planes are $\{110\}$ and so at low substrate temperatures, or when prepared with a substrate bias, the low-energy state (110) texture is obtained which promotes an epitaxial (10.1) cobalt texture. Since the atomic sizes of Cr and Co are similar, the atomic spacing of the atoms at these two surfaces approximately match and so, on a small grain size scale, an epitaxial growth results. This places the magnetic easy axis (c axis) of the HCP Co tilted approximately 28° from the film plane. Since the Cr axes are random in-plane, the in-plane magnetization components of the Co crystallites are random in-plane. On the other hand, under higher-temperature deposition conditions, it is possible to obtain (002) Cr texture from which epitaxial growth yields a (11.0) textured Co film. Since this texture calls for the HCP

FIG. 6. Cross-sectional TEM image of the SmCo/Cr interface.

c axis to lie totally in the film plane higher coercivities usually result. Less often reported, but still commonly observed, is a (10.0) Co texture which is now believed to be due to a (112) underlayer texture.²³ Peng *et al.*²² recently showed that epitaxial growth alone is not sufficient to achieve high coercivity. If the grain size of the Cr underlayer is large enough and the processing conditions are such to promote cobalt alloy bi- and quadcrystal structures,²⁴ then the effective magnetocrystalline anisotropy is compromised and, hence, the coercivity is degraded.

Due to the Cr surface roughness and grain boundaries the Co grains tends to replicate the Cr grain size. Hence, provided the Co grains do not grow together, and enable the Co to connect at the interfaces, the magnetic switching unit size is largely determined by the underlayer grain size. To decouple the grains and to keep the magnetic switching unit small various Co alloys have been studied to provide a non-magnetic grain boundary phase. For example, in CoCrTa and in CoCrPt, it has been argued that preparation of the films at elevated temperatures causes Cr segregation to the grain boundaries. However, compared to the influence of the underlayer, it is hard to conceive how this mechanism could set the basic grain size.

Clearly, it can be argued that when the lateral scale of the substrate roughness is similar to the desired magnetic unit scale media noise can be decreased.^{25,26} Likewise, a very smooth substrate could tend to promote large grain features were it not for the underlayer microstructure taking over and controlling the resulting magnetic unit size. As an example of the controlling effect of the underlayer a fairly uniform roughness results when 28 nm of SmCo is deposited upon a 100-nm (110) textured Cr layer prepared at room temperature on a smooth substrate.²⁵ Without the controlling Cr underlayer identically prepared SmCo films result in nonuniform, enlarged grains and a noisy media. The uniform roughness provided by the Cr underlayer leads to, a uniform SmCo unit size, a delineation between magnetic units, and consequently a lower-noise medium. Further evidence of this delineation is shown in the transmission electron microscope (TEM) cross section, Fig. 6. This structure is composed of a Cr underlayer, a SmCo magnetic layer, and a Cr overlayer. The underlayer grain structure clearly propagates not only into and through the SmCo layer, but continues into the Cr overlayer. A high-resolution TEM image of this film is shown in Fig. 7.

FIG. 7. High-resolution TEM cross-sectional image at the SmCo/Cr interface.

Here, the Cr grain structure is clearly evident and close examination shows the shadowing of the SmCo units at the Cr grain boundaries continuing through the film thickness. At first glance, it appears that the SmCo layer is amorphous, which is consistent with the reported high temperatures ($>600^\circ\text{C}$) needed to crystallize the films.²⁷ However, close examination shows that a large number of SmCo nanocrystallites (2–5 nm size) grow even at room temperature when prepared on the Cr underlayer. Epitaxial growth between the Cr and the SmCo interface is also weakly visible. Bright-field, plane-view TEM microstructural images of this film shows a clear separation between the grains while the selected area electron diffraction pattern shows evidence that a lattice matched crystallinity exists in the SmCo. The underlayer has strongly influenced the magnetic switching unit size and has also induced at least partial crystallinity into the, otherwise, amorphous, SmCo film. This results in the low-noise performance indicated in Fig. 2.

V. NEW MEDIA STRUCTURE APPROACH

In order to further minimize medium noise, even smaller magnetic switching unit sizes need to be achieved while more perfect crystals are needed to maintain coercivity. One approach is to use sputtered multiple epitaxial layers. Figure 8 depicts such a structure. If the substrate is assumed to be perfectly smooth, then the first sputtered layers will dominate the magnetic film's microstructure. Each of the layers can have multiple purposes, but the following gives a simplified picture of their roles: The seed layer is to provide an initial texture, while still providing a smooth surface to the underlayer. This way the underlayer texture is formed early during film growth. The underlayer is to control the fundamental grain size and, also, to transfer a high quality texture via epitaxial growth to the latter layers. The intermediate layer can provide both chemical effects and a buffer interface to promote a better Co layer texture as we shift from a BCC lattice to the HCP. The magnetic layers provide the storage mechanism while the interlayer has been used in the past to double the number of magnetic particles.^{28,29} The overlayer, overcoat, and lubricant are to provide their normal protective functions.

FIG. 8. Thin-film layer structure in novel high coercivity media with multiple magnetic and nonmagnetic layers.

We now discuss two media structures which follow this format. The first consists of an alternative underlayer with *B2*-type crystal structure.²³ The *B2* is a derivative structure of the bcc Cr and for NiAl the atomic spacing is almost identical to that of Cr thus providing a potential epitaxial match for HCP Co.²³ Because the sputtered NiAl grain size is more uniform and about half that of Cr,²³ there is the potential for smaller Co grains and lower media noise. When CoCrPt (or CoCrTa) is deposited onto NiAl or Cr underlayers, using identical processing conditions, very similar coercivities are obtained provided the NiAl is thicker. However, if even a very thin, 2.5 nm, intermediate layer of Cr is used on the NiAl then the coercivity is even greater than for the medium with a Cr underlayer. The dramatic effect of the intermediate layer is believed to be due to a smoother atomic interface resulting in a more perfect Co crystallite. Preliminary measured values of noise have shown a significant improvement.³⁰ Other evidence of the benefit of an intermediate layer is the use of a thin layer of CoCrTa between a Cr underlayer and a Pt-rich $\text{Co}_{72}\text{Cr}_{10}\text{Pt}_{18}$ alloy.³¹ By using 5-nm-thick CoCrTa as an intermediate layer on Cr, a HCP template was provided for the epitaxial growth of the larger lattice constant $\text{Co}_{72}\text{Cr}_{10}\text{Pt}_{18}$ and the coercivity increased by over 30% (>4000 Oe).

The second approach is to use a seed layer to initialize the underlayer crystal texture which may in turn enhance crystal perfection by minimizing internal lattice defects. Nakamura and Futamoto³² demonstrated that Cr could be epitaxially grown on single-crystal [001] MgO. For this *B1*-type crystal the {001} planes have the lowest surface energy.³³ Hence, we have found that even very thin layers of sputtered MgO are (001) textured. This surface matches well with the bcc Cr³⁴ to induce a strong (002) Cr texture, Fig. 9, even when the films are prepared without preheating the substrate. Coercivities greater than 4000 Oe have been achieved for CoCrPt magnetic layers grown on this structure.³⁴ A similarly impressive effect on coercivity is found when NiAl is used as the underlayer on the MgO seed layer.³⁵

FIG. 9. X-ray diffraction patterns of CoCrPt films grown on 100-nm-thick Cr underlayers sputtered onto MgO seed layers of (a) 50 nm, (b) 20 nm, and (c) zero thicknesses.

VI. BEYOND 10 Gb/in²

Here we have compared current hard disk media to experimental media approaching 10 Gbit/in.² densities. We have shown that apparent media noise is tied to the recording head field gradient as well as to the substrate and underlayer smoothness. In addition, we have outlined epitaxial procedures for developing media with both higher coercivities and smaller magnetic switching units.

It may very well be possible to continue on the current technology path to recording densities even beyond 10 Gbit/in.² However, it is hard to see how recording densities can increase another order of magnitude without a considerably different approach.³⁶ If a medium with uniformly placed magnetic units is conjectured, many of today's technical limitations are eliminated. If a bit is defined as either a single, or a fixed number of magnetic switching units, then the noise issues change from asking how many particles are in a bit to whether or not manufacturing inaccuracies spatially misplaced the magnetic units. The system noise may then be dominated by tracking and transducer sensitivity limits. Hence, a uniform array of magnetic particles, each just larger than the superparamagnetic size limit, would represent the ultimate recording medium. For uniaxial cobalt alloys, 8-nm-diameter particles centered on a 10 nm array spacing should provide stable data bits. This corresponds to a recording density of over 6000 Gbit/in.² Clearly producing this array of sublithographic particles will require novel patterning or self assembly techniques and depending upon the transducers it may be important to have a single magnetic orientation. This raises entirely new challenges for those who will develop the tracking and signal processing technologies. Nevertheless, these technologies are within the realm of imagination and lend support to a continuity of the 60% areal density growth curve.

After providing an overview of the read channel function in a magnetic disk recording system, we describe a range of possible partial-response maximum-likelihood (PRML) detection schemes. Improvements upon the current industry-standard PRML system can potentially provide substantial increases in areal density, as is shown by means of computer simulation of channel and detector.

© 1996 American Institute of Physics. [S0021-8979(96)06308-4]

I. INTRODUCTION

The past several years have seen an explosion in the use of signal processing for the magnetic recording channel. The traditional analog peak detecting read channel is rapidly being displaced by the mixed-signal (analog and digital) partial-response maximum-likelihood (PRML) read channel¹ as a means of supplementing areal density increases which are due to improved head and media components.

Implementation for PRML technology in high-end disk drives was first described in Refs. 2 and 3. Thanks to new high density integrated circuit processes and streamlining of the signal processing algorithms, PRML technology is now rapidly finding its way into mainstream low cost disk drive products which are intended for desktop and notebook personal computers.⁴

While the main portion of the areal density increase in magnetic recording will likely always come from improved heads and media, signal processing and coding can provide a significant benefit that should be exploited. A case in point is the PRML demonstration described in Ref. 5 where a 1.08 GB conventional (1,7) run-length limited (RLL) peak detection disk drive was converted into a 1.4 GB PRML disk drive. This 30% density increase was achieved using the same generation of head and disk technology as the peak detection drive.

Signal processing and coding are also providing more subtle benefits by compensating for nonidealities in the magnetic recording channel, such as thin film head undershoots,⁶ nonlinear transition shift,⁷ media defects and magnetoresistance head thermal asperities.⁸ When the signal processing is made adaptive, it can also help to compensate for manufacturing tolerances of the magnetic components such as the variation of readback pulse widths. By becoming more tolerant to component variation, adaptive signal processing can increase the number of heads and disks that can be built into one head/disk assembly with high yield. This effectively increases the capacity of a drive that can be attained at a fixed yield.

We begin in Sec. II with some background material regarding the functions of a read channel, and a brief description of how analog peak detection works. Section III is an

overview of PRML systems, including extended and generalized partial-response. Generalized partial-response holds the promise of providing optimum performance over an uncoded channel. (By "uncoded" we mean that no additional noise immunity is obtained directly from the code. A run-length code is still assumed.) In Sec. IV, we show typical areal density gains that can be anticipated as systems evolve from peak detection to more complex detectors. Section V concludes with a discussion of some options for adding a channel code as a means of increasing immunity to noise. While coding gain in the high density magnetic recording channel is difficult to attain, such codes can potentially improve upon generalized PRML when sufficient complexity is permitted.

II. BACKGROUND

A. The read channel

The function of the read channel (data receiver) is to convert the preamplifier analog output signal into the original user data. All of the proposed data receivers share some common features (Figure 1).

They consist of automatic gain control (AGC), equalization, timing recovery, bit detection, and modulation decoding. The AGC system gain normalizes the preamplifier output to the predetermined range which is expected by the bit detector. The equalizer first filters the signal to eliminate out-of-band noise and also to shape the in-band spectrum (possibly adaptively) to improve the bit detection quality. The timing recovery system locks the detector to the phase and frequency of the incoming data stream. The bit detector may consist of a simple peak detection circuit or a more complicated Viterbi detector. In either case, the bit detector recovers the encoded data that was originally written to the disk. The

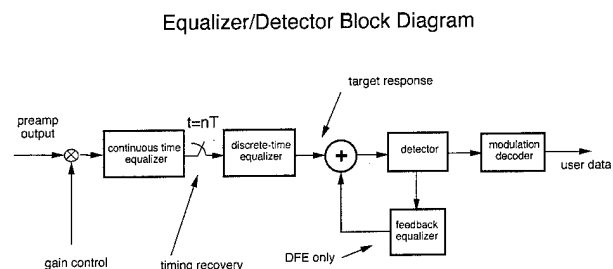

FIG. 1. Read channel block diagram.

^{a)}Electronic mail: kfisher@qntm.com, fax 408-894-3207.

modulation code usually consists of a RLL code whose "d" and "k" constraints control the minimum transition spacing on the disk and the maximum spacing between transitions. The "d" constraint impacts the head and disk design, as the magnetic components must support this minimum transition spacing. The "k" constraint is intended to ensure a minimum number of transitions on the disk, and thus enable the timing and gain loops to accurately track the signal. The timing loop and gain recovery, while important, are not central to the subsequent material and will not be discussed further.

B. Peak detection

Peak detection is typically accomplished by means of a differentiator and threshold detector. If during a timing window the undifferentiated peak is above a threshold at the same time that the differentiated wave form is at zero, then a peak (noted as a binary "1") is declared. Otherwise no peak (or "0") is indicated. Peak detect systems work best when adjacent pulses do not interfere. The interference of adjacent pulses (equivalently "peaks") is called intersymbol interference (ISI).⁹

The main function of the equalization and coding in this case is to eliminate interference between peaks. This aim is generally accomplished by means of a rate 2/3 (1,7) RLL code and a "pulse slimming" equalizer. The (1,7) code effectively increases the spacing in time (or on disk) between peaks by 33%, at the expense of the code rate.

In spite of the RLL code, it is inevitable that the unequalized peaks will begin to interfere as densities increase. To improve detection performance, the equalizer is used to boost the high frequencies and thus decrease the width of the pulses. In this case, the high frequencies are boosted until a tradeoff between residual ISI and noise enhancement is attained.

III. PRML SYSTEMS

Partial-response systems differ from peak detect systems in that the amount of required high frequency boost can be dramatically reduced and the stringent $d=1$ RLL requirement is eliminated, provided that an appropriate PR target is used.¹⁰ By permitting $d=0$, much higher code rates, such as 8/9 or 16/17, are possible. The higher code rate reduces the effective $pw50/T$ at the detector, where $pw50$ is the pulse width at 50% amplitude and "T" is bit time on the disk. Unless otherwise stated, we assume all PRML systems use a (0,k) code.

Partial-response provides a means for improving areal densities, as the amount of noise in the detector is reduced. The ISI need not be eliminated but is instead controlled. A maximum-likelihood (ML) detector is then used to extract the original recorded data from the PR wave form. The ML detector considers a span of channel outputs during the decoding process, and thus uses the ISI to its advantage.

A. Partial-response class IV

Partial-response class IV (or PR4), the *de-facto* industry standard, was a natural first step when departing from peak detect systems.^{1,11,12} PR4 is characterized by its dibit response

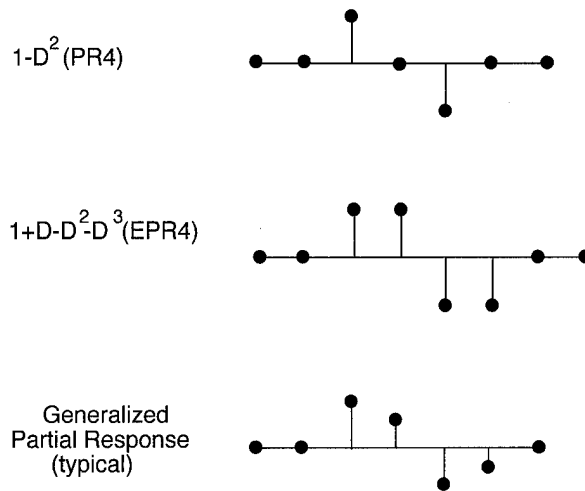

FIG. 2. Dibit response for PR4, EPR4 and generalized partial-response.

sponse (response to two adjacent transitions), which is $1 - D^2 = (1 + D)(1 - D)$, where D is a unit delay relative to the write clock (Figure 2). PR4 provides a reasonable match to the magnetic channel at moderate user densities in the range of $pw50/T = 2.0$.

Viewed from the frequency domain, the PR4 response has spectral nulls at both zero and the Nyquist frequency which matches the magnetic channel's failure to pass low frequencies and the inherent high frequency losses at high densities (Figure 3). The required amount of high frequency noise boost is thus minimized.

PR4 was a natural first step for implementation reasons as well. The $1 - D^2$ partial-response can be decomposed into two interleaved $1 - D$ channels operating at half-rate. It is thus possible to have two (simpler) detectors running at half-rate as opposed to one high rate magnetic detector. This is a distinct advantage in high data-rate magnetic recording systems. One negative aspect of maximum-likelihood detection is that there is often significant decoding delay, as it is necessary to look at a span of the disk samples to make optimal decisions

FIG. 3. Frequency response for some partial-response polynomials and the magnetic channel at density $pw50/T = 2.3$.

TABLE I. PR4 channel output sample levels.

PR4 output	Channel inputs	
	b_k	b_{k-2}
0	-1	-1
-2	-1	+1
+2	+1	-1
0	+1	+1

(decoded disk data). This is not acceptable for decision directed timing recovery and gain control, which need low latency feedback loops to function properly. In PR systems, it is thus necessary to make preliminary decisions on the equalized wave form before the maximum-likelihood detector. In this regard, PR4 has another distinct advantage. As shown in Table I, the PR4 signal has only three levels. A simple threshold detector can easily resolve these three levels, thus resulting in adequate quality decisions for gain and timing.

B. Extended PRML

To achieve higher user densities, new PR targets that better match the inherent magnetic channel are needed. In an attempt to better match the high frequency losses that are present at very high densities, a class of extended partial-responses, $(1-D)(1+D)^N$, has been proposed,¹⁰ for integers $N > 0$. Two notable choices from this class are $(1-D) \times (1+D)^2 = 1 + D - D^2 - D^3$, which is called EPR4, and $(1-D)(1+D)^3$, which is called EEPR4. Higher orders than $N=3$ are at this point deemed impractical.

EPR4 is a straightforward extension of PR4. The second-order spectral null at the Nyquist frequency results in a reasonable match to the channel at densities of $pw50/T=2.5$. The primary drawbacks to EPR4 are the increased complexity ML detector (more than twice the complexity and twice the required speed compared with the PR4 detector), and the difficulty in maintaining good timing recovery and gain control from the preliminary five-level EPR4 decisions. As discussed earlier, preliminary decisions are necessary because of the decoding delay in the ML detector. In order to overcome these difficulties, a number of suboptimal "postprocessor" approaches to EPR4 decoding have been proposed.^{13,14} In general, the postprocessor assumes a PR4 ML detector as a preprocessor. By using knowledge about the magnetic channel and the types of error events that are common in the PR4 ML detector, the postprocessor can correct those errors that would not have occurred in the EPR4 ML detector. Performance of a suboptimal detector is tightly coupled to the specific implementation and magnetic channel assumptions. In subsequent figures, we assume true EPR4 ML detection.

EEPR4 has been proposed in combination with a rate 2/3 (1,7) code.⁶ Assuming that a (1,7) code is required by head and media constraints, EEPR4 provides a good match to the channel at the higher $pw50/T$ values that are required by the low rate code. While a ML detector for EEPR4 is twice as complex as the EPR4 detector, some simplifications result when taking the (1,7) code constraints into account. Coinci-

dentally, these code constraints also improve the ML detector performance. Probably the biggest drawback to EEPR4 is the high clock rates which will result from the low code rate.

C. Generalized PRML

Until this point, only integer coefficient partial-response polynomials have been mentioned. By permitting the PR target, first, to be nonintegers and, second, to vary with the channel response, a better match to the channel is possible (see the DFE case of Fig. 3), which can result in additional performance gains. This possibility has been proposed for magnetic recording in many different forms, including fixed-delay tree search (FTDS)¹⁵ and nonlinear reduced-state sequence estimation (RAM-RSE).¹⁶

It is not obvious which choices of polynomials will result in superior performance. The mean-square noise-whitening matched filter (MS-WMF) is known from communication theory to be an optimum equalizing filter. Quite fortunately, a minimum mean square error decision feedback equalizer (MMSE-DFE) turns out to naturally include this filter as its forward equalizer.¹⁷ In this case, the forward equalizer output will have a dibit response of the form $1 + w_1 D + w_2 D^2 + w_3 D^3 + \dots$ for real-valued w_i . A DFE in its simplest form will use past decisions to cancel the tail $w_1 D + w_2 D^2 \dots$ and use a simple threshold at zero to resolve to two possible decisions, +1 and -1. This tail cancellation is the source of the term "decision feedback." As greater performance is required, the threshold detector is replaced by a ML detector which uses part or all of the ISI in the tail to resolve the most likely recorded data. The remaining portion of the tail that is not used in the ML detector will continue to be cancelled by decision feedback. In the case of a varying channel, the DFE may be made adaptive.

With sufficient complexity (i.e. number of polynomial terms used), the DFE with a ML detector provides the best attainable performance for a (0,k) coded system that does not have any "coding gain."

IV. POTENTIAL AREAL DENSITY GAINS

We project the areal density gains that are possible using currently proposed signal processing techniques. We start with a basic peak detect system. From the published demonstrations described earlier (Sec. I), a 30% areal density improvement is shown to be achievable in the transition to PR4 ML detection. Since demonstrations like this are not available for more advanced systems, we must rely on computer simulations for further projections.

These simulations were done using a linear superposition model. We used an experimental magnetoresistive head response normalized so that its peak amplitude is one and we included a small amount of nonlinear transition shift. Media noise is assumed to be accurately described by a microtrack model¹⁸ with a magnetization pattern, $m(x) = \tanh(2x/(a\pi))$, and electronics noise is assumed to be additive Gaussian noise. The system parameters are summarized in Table II.

In order to compare the detection schemes at different track and linear densities, SNR_e , and SNR_m , the signal to noise ratio of the electronics and media noise, respectively,

TABLE II. Simulation parameters.

System parameter	Value
User data rate	150 Mbits/s
$pw50$ (seconds)	16.7 ns
$pw50$ (inches)	5.7 μ in.
Reference SNR _e	30.5 and 29 dB
Model	microtrack
Magnetization pattern	$m(x) = \tanh(2x/(a\pi))$
Number of microtracks	20,35,50,65,80
Values of a	0.35 μ in., 0.60 μ in.
Nonlinear transition shift	0.228 μ in.
Write asymmetry	0.095 μ in.
Anti-aliasing filter	7th order Butterworth
Code	(0,4) RLL ideal (rate 0.96)
Length of feedforward filter	20 taps symbol spaced
Span of feedback for RAM-RSE	10T
Detectors	PR4 ML, EPR4 ML, RAM-RSE3 (8 state)

were scaled appropriately.¹⁹ The SNR_e was measured as the peak of an isolated step response squared divided by the power of the Gaussian noise in a 0–50 MHz band. We can write SNR_e in terms of a reference, SNR_{e,0} as

$$\text{SNR}_e = \text{SNR}_{e,0} \left(\frac{w}{w_0} \right)^2,$$

where w is the track width. Because of the way we defined SNR_e, its value does not decrease as linear density grows, though in simulation results presented here, the average signal power (rms) does fall and the average electronics noise power does grow linearly as linear density rises. Similarly we write SNR_m in terms of a reference, SNR_{m,0} as

$$\text{SNR}_m = \text{SNR}_{m,0} \left(\frac{w}{w_0} \right) \left(\frac{\eta_0}{\eta} \right),$$

where $\eta = pw50/T$ is the linear density. We neglect any micromagnetic nonlinear effects as transitions get closer and neglect any inter-track interference that may result from a higher track density.

FIG. 4. Track width vs linear density for a disk dominated by electronics noise (solid) and media noise (dashed).

FIG. 5. Areal gains.

The scaling of media noise power (or of SNR_m) with linear and track density is a natural property of the microtrack model. Varying track width is accomplished with the microtrack model by changing the number of microtracks. For the results presented here, 50 microtracks corresponded to a normalized track width of one. For example, a track 50% narrower (twice the track density) would have only 25 microtracks.

For density gain projections, we chose to compare PR4 ML with EPR4 ML and the RAM-RSE with eight states. The RAM-RSE is a nonlinear DFE with an ML detector. We know of no currently proposed detectors that outperform the RAM-RSE (without coding gain).

Simulation results are depicted in Fig. 4 under the assumptions listed in Table II. A normalized track width of one is the point of reference. There are two sets of results, one for which electronics noise dominates (solid lines) and one where the media noise is stronger (dashed lines). The total amount of noise is the same for both cases. At the reference track density, the ratio of electronics to media noise per transition was 3:1 and 1.5:2 for the two results respectively. The curves represent a trade-off between linear density and track width holding the bit error rate constant at 10^{-5} .

For both sets of three curves, with the scaling described previously, we assume the same head and disk: only the track width and linear density are varied. In this way, the projected gains are the result of signal processing only and do not include any other technology improvements.

We see that it is advantageous to make the track width as narrow as possible. Even a substantial drop in SNR caused by narrower tracks has only a relatively minor affect on the achievable linear density. We assume, therefore, that the track width is fixed, limited by the accuracy of servo tracking, erase bands, and other physical factors, and summarize achievable density increases in Fig. 5. A range of linear density improvement is seen as we change the reference track density. The most advanced uncoded detection schemes can improve upon peak detection by between 45% and 60% and upon PR4 ML by about 30%.

V. CODING GAIN

Coding gain is achieved by increasing the minimum distance between all pairs of channel output sequences thus

FIG. 6. "Water pour" spectrum assuming a Lorentzian impulse with $pw50$ as in Table II and $SNR_c = 21$ dB, power spectral density of an MSN code at a coded density of $pw50 = 3.5T$, and the spectrum of the Lorentzian impulse response.

making it easier to distinguish between them. In recording, this is typically done by selectively removing input strings from usage in the channel and taking this into account in the ML detector.

Achieving coding gain is especially difficult in the magnetic recording channel for several reasons. First, excluding some strings from usage in the encoder results in code rate loss, which increases the effective $pw50/T$ at the detector. In order for a code to be effective, the coding gain needs to be significantly greater than the loss due to increasing the density. This suggests high-rate codes, which are usually quite complicated to implement. Second, the channel itself acts as a code by introducing memory into the channel at the equalizer output. The performance evaluation of a code must explicitly take into account the combined impact of the channel and code. Trellis codes for the PR4 channel have been proposed,^{20,21} but the relatively low code rate has as yet limited their use. A RLL (1,7) code may also be viewed as distance enhancing but its low code rate far outweighs its coding advantage. While higher rates are possible, complexity has thus far been an impediment.

Although we have not yet found a coding scheme that offers significant benefits over the best uncoded detection, communication theory indicates room for improvement.²² Viewing the disk drive channel as a linear ISI communication channel with white Gaussian noise and continuous, Gaussian inputs, the maximum achievable data rate is obtained when the power spectral density of the input sequence roughly matches that of the impulse response of the channel. This is the "water pour" spectrum whose power spectral density, $P(f)$, at frequency, f , normalized to $1/T$ maximizes

$$C = \frac{1}{2} \int_{-1/2}^{1/2} \log_2[1 + SNR(f)P(f)] df,$$

where C is the capacity of the discrete-time channel in bits/sample over the Nyquist frequency band and $P(f)$ is subject to some overall power constraint.²³

It is not possible to store a continuous input sequence on a disk drive, however, it is possible to shape the spectrum of the binary input sequence.²⁴ For example, in Fig. 6, we compare the spectrum of a matched spectral null (MSN) trellis code²¹ with the capacity achieving water pour spectrum having made the previous assumptions. Intuitively, it makes sense to store a sequence whose spectral content is high where the channel has the most power. Unfortunately simply writing an input pattern whose spectrum matches the water pour spectrum is not enough to achieve capacity. The MSN code's 3 dB coding gain is nearly completely forfeited to the rate loss at high linear densities.

As long as the power spectrum of the input sequence matches that of the water pour distribution, it is theoretically possible to design a capacity achieving system even with a binary input constraint if the number of transitions per symbol is allowed to grow.²⁵ For example, a pattern written with transitions spaced at $T/4$ but with only one symbol per T can nearly achieve capacity. From another perspective, as the input resolution increases, there is more freedom to shape the spectrum and to add coding. This suggests creating lower rate matched-spectral codes with higher input resolution.

As we move transitions closer together, or simply increase the resolution but maintain a minimum transition spacing, nonlinear properties of the head and media will undermine any coding gains. Future codes that are both able to use the best parts of the channel's spectrum without violating the properties of the magnetic media and that offer more gain will provide the only long-term solution for improving upon generalized partial-response.

Head/disk tribology: Toward 10 Gb/in.² (invited) (abstract)

B. Marchon

Seagate Technology, Fremont, California 94538

As the race to ever increasing areal densities and lower flying heights becomes more ferocious year after year, the need for an improved understanding of the various physical and chemical processes taking place at a sliding head/disk interface becomes more urgent. This talk will review the various aspects of thin film media technology that will become essential components of a 10 Gb/in.² interface. Modeling of surface topography and its relationship with glide and stiction properties will be addressed. Recent advances in overcoat and lubrication technology will be assessed, and attempts to decrease magnetic spacing and increase durability and flyability will be discussed. Finally, the concepts of near- and/or full-contact recording and their feasibility will be reviewed. © 1996 American Institute of Physics. [S0021-8979(96)45208-0]

Quantum oscillations of properties in magnetic multilayers (invited)

G. Bayreuther, F. Bensch, and V. Kottler

Institut für Angewandte Physik, Universität Regensburg, 93040 Regensburg, Germany

An oscillatory interlayer exchange coupling observed in many sandwich and multilayer films can be understood as an interference effect of electron waves partially reflected at each interface with spin dependent reflection coefficients. Consequently, we might expect all magnetic properties in some way related to the density of states to oscillate as a function of the magnetic and nonmagnetic layer thickness. In order to experimentally test this concept we have measured different magnetic properties of Ni/Au multilayer films prepared by magnetron sputtering on glass substrates. The Ni thickness was kept constant at $t_{\text{Ni}} = (7.3 \pm 0.5) \text{ \AA}$ while the Au layer thickness was varied between 4 \AA and 80 \AA . The films had a coherent fcc structure with (111) texture. The saturation field and the remanence oscillate as a function of t_{Au} with a period which agrees well with a theoretical value calculated from the bulk Fermi surface of Au and proves that indeed an oscillatory exchange coupling is present. The Curie temperature shows oscillations with t_{Au} clearly correlated with the exchange coupling constant, J : T_C oscillates like the absolute value of J . This behavior is indeed expected from mean field theory. Similar oscillations are found for the spin wave parameter and the ground state magnetic moments. The variation of the exchange coupling with temperature and the role of inhomogeneities for the interpretation of the experimental data are discussed. © 1996 American Institute of Physics. I. INTRODUCTION

Total or partial confinement of itinerant electrons in a solid in one or more dimensions leads to quantized states. These in turn produce a variety of phenomena not observed in bulk material with macroscopic extension. The most widely studied class of material in this respect have been semiconductors: structures fabricated in the form of two-dimensional quantum wells, of quantum wires or quantum dots show a wealth of novel effects in their electronic, optical or transport properties. A simple picture to describe these consequences of electron confinement is the following: at each interface between different materials the moving electron experiences an abrupt change of potential. This is equivalent to a change of the index of refraction for the electron wave causing its partial reflection and partial transmission through the interface. In a layered structure, all the reflected and transmitted electron waves will interfere. Under certain conditions for electron wavelength, layer thickness, and phase shift upon reflection the interference will be constructive or destructive giving rise to oscillations of the density of states as a function of, e.g., layer thickness and in many cases to oscillations of related properties.

The same scenario can be applied to metallic multilayers consisting of ferromagnetic layers separated by nonmagnetic interlayers. An important extension of this simple picture now is brought in by the fact that the (complex) reflection coefficient is different for the two possible spin orientations of the moving electron if the material at one side of the boundary (or both) is magnetically ordered.

In a natural way this general concept leads to a number of phenomena which are to be expected in magnetic layer systems: (i) quantum well states in multilayers and even in nonmagnetic overlayers should be spin polarized; (ii) the to-

tal electron spin polarization, i.e., the projected magnetic moment per atom in the (itinerant) ferromagnetic layer should be affected by the layer structure and, in particular, should be an oscillatory function of the nonmagnetic interlayer thickness; (iii) a similar oscillatory behavior is expected for all magnetic properties which are related to the spin dependent density of states in a direct or indirect way like magnetic anisotropy and magneto-optic effects which are both a consequence of spin-orbit coupling; (iv) the total energy of a multilayer system will depend on the relative magnetization directions in adjacent ferromagnetic layers for a given combination of layer thickness, or in other words, the difference of the total energy between parallel and antiparallel alignment will oscillate as a function of layer thickness. This is the well known oscillatory indirect interlayer exchange coupling; (v) other magnetic phenomena which are related to the interlayer exchange coupling directly, e.g., spin wave excitations, or indirectly like the giant magnetoresistance effect (GMR) are also expected to show oscillations with increasing layer thickness.

Historically, the starting point for the study of such quantum oscillations in magnetic multilayers was the discovery first of an antiferromagnetic¹ and later of an oscillatory interlayer exchange coupling² in Fe/Cr layered structures. The interlayer exchange and the related GMR effect, which are certainly the most spectacular findings in magnetism during the last decade, have also been the most widely studied subjects in magnetic materials recently. A comprehensive theoretical description of interlayer exchange coupling based on the interference of electron waves has recently been given by Bruno.³ It is pointed out there that this general concept indeed comprises the different model descriptions proposed in the literature as special cases. A generalization of the concept even allows to explain the exchange coupling across

nonmetallic interlayers. In addition to the well established correlation between the oscillation periods and the Fermi surface of the interlayer material⁴ also an oscillatory dependence of the coupling strength on the thickness of the *ferromagnetic* layer is expected in this framework; this indeed was found subsequently in several experiments.^{5,6}

In the literature a large number of experimental and theoretical studies can be found on topics (iv) and (v) mentioned above; most of them are focused on the influence of layer thickness and structure, interface sharpness, chemical composition, etc. on interlayer coupling and magnetoresistance. However, relatively few results have been reported concerning the other predictions stated above. The existence of quantum well states with spin dependent density of states in Cu overlayers on Co and Ag on Fe has been demonstrated by photoemission and inverse photoemission experiments.⁷⁻⁹ An indication of an oscillating magnetic anisotropy of Co ultrathin films successively covered with a nonmagnetic metal (Au, Cu, Pd, etc.) of increasing thickness has been seen in several experiments.¹⁰⁻¹² Recently, oscillations of the Kerr rotation angle from an ultrathin Co film as a function of the thickness of a Au overlayer have been observed and related to spin polarized quantum well states in the Au.¹³ On the other hand, oscillations of ground state magnetic moments and the Curie temperature have not been reported until now.

Within the category of magnetic properties directly related to interlayer exchange coupling, the shape of the magnetization curve is by far the most widely used criterion for the presence of this indirect coupling: low remanence is often interpreted as an indication of antiferromagnetic coupling and the saturation field can directly provide the coupling strength in the antiferromagnetic case. Brillouin light scattering and FMR are also affected by interlayer coupling and can be used to evaluate the coupling strength.

Thermal spin wave excitations are closely connected with exchange coupling between spins. Within the Heisenberg model of exchange interaction between nearest neighbors the spin wave stiffness constant is proportional to the (average) exchange integral and, therefore, should be modified by the presence of an interlayer exchange coupling. Such an effect has indeed been observed in Fe/Ag multilayer films¹⁴ where an oscillation of the spin wave parameter, B , with Ag layer thickness was found.

In an analogous way, the Curie temperature, T_C , of a ferromagnet is proportional to the average exchange energy per atom within mean field theory (MFT). Consequently, we might expect the Curie temperature of a periodic stack of ferromagnetic and nonmagnetic layers to oscillate as a function of nonmagnetic layer thickness. This can be seen if we assume the component of the total exchange energy density due to interlayer coupling, $E_{\text{ex}}^{\text{interl}}$, to be given by

$$E_{\text{ex}}^{\text{interl}} \propto -J_1 \cdot \vec{M}_a \cdot \vec{M}_b \quad (1)$$

with an interlayer coupling constant J_1 oscillating between positive and negative values depending on the nonmagnetic layer thickness t_i .

A change in sign of J_1 will reverse the relative alignment of the magnetizations \vec{M}_a, \vec{M}_b of the ferromagnetic layers

from parallel to antiparallel or vice versa in the equilibrium state. So, $E_{\text{ex}}^{\text{interl}}$ is always negative and depends only on the absolute value of J_1 . If we now assume the Curie temperature to be proportional to the total exchange energy per atom which is the sum of interlayer and intralayer coupling energy, then we expect T_C to oscillate as a function of the interlayer thickness with a period of oscillation half of the period of J_1 . However, no experimental verification of this effect has been reported in the literature previously.

In order to check the general validity of the concept outlined above we have investigated several magnetic properties of a series of Ni/Au multilayer films. Ni was chosen because of its relatively low Curie temperature; by sufficiently reducing the Ni layer thickness the Curie temperature can be reduced below room temperature. This allows to eliminate the risk of irreversible structural changes when measuring around the critical point. For the nonmagnetic layer Au was used because it can easily be grown with a strong (111) texture on glass substrates even by sputtering. The magnetization curves showed oscillations of the remanence and the saturation field with the period of the Au layer thickness theoretically predicted for the interlayer exchange coupling through Au(111), J_1 . The Curie temperature showed pronounced oscillations with a period like $|J_1|$ in accordance with the mean field argument given above.¹⁵ Oscillations of the spin wave parameter were observed which are clearly correlated with the oscillations of T_C . A similar behavior was found for the ground state magnetic moments.

II. EXPERIMENT

For sample preparation dc magnetron sputtering sources were used in an UHV based sputtering system. The argon pressure during deposition was $6 \cdot 10^{-3}$ mbar, the sputtering rate was 0.27 nm/s for Au and 0.13 nm/s for Ni.

To study the interlayer coupling a series of Au(30 nm)/[Ni(t_{Ni})/Au(t_{Au})]₁₀/Au(30 nm) multilayers ($t_{\text{Ni}}=0.73 \pm 0.05$ nm, $t_{\text{Au}}=0.4-8.0$ nm) was deposited on glass substrates at room temperature. A second series of samples was prepared with $t_{\text{Ni}}=0.4-1.4$ nm and $t_{\text{Au}}=8.0$ nm ("uncoupled films") in order to determine the dependence of T_C on the thickness of the Ni layers alone. The Au layer is expected to be thick enough to exclude any interlayer exchange coupling. The data of this series were used to correct for the effect of the variation of t_{Ni} (± 0.05 nm) on T_C within the first series (see below).

The total amount of Ni and Au of each sample was determined by x-ray fluorescence analysis (XFA) and converted into a nominal layer thickness assuming the bulk densities. The statistical error is ± 0.006 nm for Ni and ± 0.016 nm for Au. The variation of the Ni thickness within the first series of ± 0.05 nm was due to the finite precision of the shutter operation.

Small angle x-ray diffraction and high resolution electron microscopy (HREM) were used to study the structure of the films. The layer thickness or multilayer period determined in this way agreed with the XFA data with an error below 1%. The layer structure turned out to be quite uniform. The films are polycrystalline with a pronounced (111) texture. For $t_{\text{Au}} \leq 2$ nm a coherent fcc structure is observed

FIG. 1. Saturation field, $H_{\text{sat}}^{80\%}$, and magnetic remanence, m_R/m_S , versus Au layer thickness, t_{Au} , at 10 K. Dashed lines mark the behavior expected without interlayer coupling. Solid lines represent a spline fit and serve as a guide for the eye.

throughout the whole multilayer although the lattice parameters of Ni and Au differ by about 14%. This means that there is significant lattice strain in the film plane which is tensile for Ni and compressive for Au. So one might expect the Au lattice to be expanded and the Ni lattice to be compressed perpendicular to the plane; however, this is not observed. A more detailed discussion of thickness dependent strain in Ni/Au multilayers and its influence on magnetic properties is given by Nakayama *et al.*¹⁶ and Childress *et al.*¹⁷

Magnetic measurements were carried out using a SQUID magnetometer at temperatures between 10 K and 400 K in magnetic fields up to 50 kOe.

III. EXCHANGE COUPLING

Like in previous studies magnetization curves of the films were used to detect the presence of an interlayer exchange coupling. The magnetic field was always applied parallel to the film plane since all samples exhibit a magnetic easy plane anisotropy. The spontaneous magnetic moment, m_S , was determined by linear extrapolation of the saturated part of the magnetization loop between 2 and 10 kOe back to zero field. The remanent moment, m_R , is the magnetic moment in zero field after saturation at 50 kOe. $H_{\text{sat}}^{80\%}$ is taken as the external magnetic field for which the sample moment reaches 0.8 m_S . 80% saturation has been chosen for convenience because this value can be determined with much better precision than the real saturation field H_{sat} . The latter is approximately twice the value of $H_{\text{sat}}^{80\%}$ for all samples.

The plot of the saturation field, $H_{\text{sat}}^{80\%}$, and the magnetic remanence, m_R/m_S , at 10 K as a function of Au layers thickness, t_{Au} , (Fig. 1) clearly shows an oscillatory interlayer coupling. The observed oscillation period, $\Lambda_{\text{exp}} = (1.15 \pm 0.1)$ nm, is in good agreement with the value $\Lambda_{\text{theor}} = 1.135$ nm theoretically predicted on the basis of experimental data on the Fermi surface of bulk gold.⁴ The additional continuous increase of the saturation field with increasing Au layer thickness is probably due to local magnetic anisotropies caused by the increasing strain in the Ni layers. It is also observed that m_R/m_S does not reach zero at its minima which correspond to the strongest antiferromagnetic coupling. This can be ex-

FIG. 2. Determination of the Curie temperature, T_C , by two different methods: (a) linear extrapolation of $m^2(T)$ to $m=0$; (b) minimum of dm/dT .

plained by a certain uncorrelated interface roughness which creates local thickness fluctuations. The presence of such a roughness can also be concluded from x-ray diffraction and HREM data. As a consequence, interface regions with ferromagnetic coupling will coexist with antiferromagnetically coupled ones giving rise to a finite remanence.

From the interlayer coupling contribution to the saturation field, $H_{\text{sat}}^{\text{eff}}$ (Fig. 1), we can estimate the interlayer coupling energy per unit area, I_1 : if we assume that for $H = H_{\text{sat}} = 2H_{\text{sat}}^{\text{eff}}$ the interlayer exchange energy is balanced by the magnetostatic energy of the Ni layers in the applied field we get $I_1 \approx 0.004$ erg cm⁻² for the first antiferromagnetic maximum at $t_{\text{Au}} = 1.2$ nm.

IV. CURIE TEMPERATURE

The Curie temperature was determined from the magnetic moment vs temperature $m(T)$ measured with the SQUID magnetometer. The data were taken at decreasing temperature in the presence of a constant magnetic field of 100 Oe parallel to the film plane. This approach will also work in the case of antiferromagnetic coupling provided that the moments do not completely cancel; this does not happen in practice. From $m(T)$ curves T_C is evaluated by two different methods as shown in Fig. 2: either by linear extrapolation of $m^2(T)$ to $m=0$ as suggested by molecular field theory [Fig. 2(a)] (fitting with $m \propto [(T_C - T)/T_C]^\beta$ with T_C and β as free parameters yields similar results but with less precision) or by the minimum of dm/dT [Fig. 2(b)]. The first value is expected to be closer to the true transition temperature than the second one which, however, can be determined with higher accuracy. Both values are shifted by a constant amount of (5 ± 0.5) K relative to each other for all films. Therefore, the difference is irrelevant for the question of a possible variation of T_C with the Au layer thickness. T_C values discussed below were determined according to Fig. 2(b).

The dependence of the Curie temperature on the thickness of the Ni layers, t_{Ni} , has been determined using the *uncoupled films* mentioned above. The results are shown in Fig. 3. In order to interpolate between the experimental data points, the following power law is used:

$$T_C(t_{\text{Ni}}) = T_C(\infty) \cdot [1 - (t_{\text{Ni}}/t_0)^{-\lambda}], \quad (2)$$

FIG. 3. Curie temperature, T_C , of Ni/Au multilayers with $t_{Au}=8$ nm (uncoupled films) as a function of Ni layer thickness, t_{Ni} . The uncertainty of T_C is ± 3 K. The dashed line represents a fit according to Eq. (2).

suggested by scaling theory.¹⁷ A numerical fit to the experimental data yields $\lambda=0.63\pm0.02$ and $t_0=(0.422\pm0.009)$ nm while $T_C(\infty)=630$ K was held constant. These values are in excellent agreement with those found by Childress *et al.*¹⁸ As already mentioned above, within the first series of films with a nominal Ni thickness of 0.73 nm a certain variation of the Ni layer thickness could not be avoided (± 0.05 nm). In order to eliminate the effect of the Ni layer thickness on T_C the data of Fig. 3 were used. It was assumed that the variation of T_C with t_{Ni} , dT_C/dt_{Ni} , is the same for all multilayers. This would not be exactly true for films with thin Au layers if T_C is indeed affected by interlayer exchange. However, for all films the intralayer exchange energy is still much larger than the interlayer exchange energy and, therefore, the procedure used will be approximately correct. This point will be discussed further at the end of this section.

The corrected Curie temperatures, $T_C(t_{Au})$, of all samples from the first series are plotted in Fig. 4(a) in comparison with the magnetic remanence, $m_R/m_S(t_{Au})$ [Fig. 4(b)], as a function of Au layer thickness. It is apparent that T_C does not increase monotonically with decreasing thickness of the Au interlayer but rather shows pronounced oscillations. There is an unambiguous correlation between the Curie temperature, T_C , and the remanence, m_R/m_S : maxima of T_C are observed for those values of t_{Au} where m_R/m_S has a maximum or a minimum; minima of T_C occur wherever the interlayer exchange coupling is zero, i.e., when m_R/m_S equals the value observed for very thick Au interlayers. It means that the Curie temperature of the Ni layers is enhanced both by a ferromagnetic and an antiferromagnetic interlayer coupling. This is exactly what is expected from the argument given above that the interlayer exchange energy has always the same sign both for ferro- and antiferromagnetic interlayer coupling. Furthermore, this type of oscillation with a shorter period compared to the oscillation of J_1 supports the conclusion that the observed T_C oscillation is not an artefact produced by the method used to determine T_C because otherwise we might expect the same oscillation period for m_R (i.e., J_1) and T_C .

We can also rule out a possible interpretation of the oscillatory Curie temperature as a consequence of some structural changes with increasing Au layer thickness by the following arguments: (1) if a structural change affects T_C it is hard to understand how this could cause an oscillation of T_C ; (2) the close correlation between the oscillations of T_C and of the remanence and saturation field is a strong indication of a

FIG. 4. Magnetic properties of exchange coupled Ni/Au multilayer films as a function of Au interlayer thickness, t_{Au} . The thickness of the Ni layers is kept constant with $t_{Ni}=0.73$ nm. Small variations of the Ni layer thickness have been corrected as described in the text. (a) Curie temperature, T_C , (b) remanence, m_R/m_S ; (c) effective spin wave parameter, B ; (d) average ground state magnetic moment per Ni atom, $\langle\mu\rangle$. Horizontal dashed-dotted lines represent the respective values for uncoupled films, i.e., for $t_{Au}=8$ nm. The dashed (dotted) vertical lines indicate interlayer thicknesses where the absolute value of the interlayer coupling strength is expected to have a maximum (zero) amount. Solid lines are a guide to the eye.

common origin of both phenomena; (3) the observed oscillation period agrees well with the value which was theoretically predicted on the basis of the Au Fermi surface;⁴ (4) oscillations of the spin wave parameter, B , and the magnetic ground-state moments of Ni have been found from magnetization measurements at temperatures far below T_C which are strongly correlated with the T_C oscillations. These will be discussed in the next section.

Mean field theory predicts the critical temperature of a ferromagnet to be related to the exchange energy per magnetic atom, ε_{ex} , according to $k_B \cdot T_C \approx \varepsilon_{ex}$ for an fcc lattice with $S=1$. This allows us to estimate the interlayer coupling energy per atom from the variation of the Curie temperature, $\Delta T_C \approx 40$ K, between $t_{Au}=1.2$ nm and $t_{Au}=1.3$ nm resulting in $\varepsilon_{ex}^{interlayer} = k_B \cdot \Delta T_C = 3.4$ meV.

For the calculation of the coupling energy per unit area, I_1 , we need the areal density of those Ni atoms which are responsible for the enhancement of T_C due to interlayer exchange coupling. The simplest assumption is that all Ni atoms are equally affected by interlayer coupling; however, it might be more realistic to assume that only a certain part of

the Ni atoms experience the maximum coupling strength which determines T_C . Using the first assumption we obtain a [coupling energy density of $I_1=36$ erg/cm². This value seems unrealistically large, i.e., several orders of magnitude larger than the coupling strength derived from the saturation field (0.004 erg/cm²) and also much larger than theoretical values⁴ (e.g., 0.4 erg/cm²).

On the other hand, we know from the measurement of the remanence discussed above that there is no homogeneous antiferromagnetic coupling in our multilayer films. In this case local values of ϵ_{ex} will have a broad distribution and the Curie temperature will be determined rather by the maximum of ϵ_{ex} than by its average value. Therefore, I_1 will be drastically smaller than the first estimate. A more elaborate theory of phase transitions in exchange coupled multilayer films should also consider the crossover from a 2-dimensional to a 3-dimensional phase transition when the interlayer coupling is switched on.

A final remark must be made to the procedure applied above to correct for the variation of the Ni layer thickness within the series of coupled multilayers. After it has been shown that T_C is indeed affected by interlayer exchange it is also clear that Eq. (2) cannot hold in general for exchange coupled multilayers because the coupling strength is known to depend also on the ferromagnetic layer thickness.^{3,5,6} Once this dependence is measured for Ni/Au multilayers a complete discussion of the Curie temperature as a function of t_{Ni} and t_{Au} will be possible for the coupled films.

V. SPIN WAVES AND GROUND STATE MAGNETIC MOMENTS

The spontaneous magnetic moment of the coupled multilayer films, m_S , was determined from the magnetization loops by extrapolation to $H=0$ as described above. The temperature dependence $m_S(T)$ was fitted by two different expressions which have been proposed in the literature for spin wave excitations in thin films, i.e.,

$$m_S(T) = m_S(0) \cdot (1 - B \cdot T^{3/2})$$

and

$$m_S(T) = m_S(0) \cdot [1 - A_0 \cdot T \cdot \ln(A_1 \cdot T)].$$

The validity of spin wave theory being limited to sufficiently low temperature, the discussion was restricted to $T < T_C/2$.

Within the experimental uncertainty the $T^{3/2}$ law valid in bulk ferromagnets gave an equally good fit to the data as a $T \ln T$ law which was suggested in the literature^{19,20} for monolayer films. The approximate validity of an "effective $T^{3/2}$ law" for surfaces and ultrathin films has been pointed out before.²¹ Therefore, both the parameter B from the $T^{3/2}$ fit and the interlayer coupling constant, J_1 , derived from a $T \ln T$ fit according to Qiu *et al.*²⁰ have been calculated. It turned out that a $T \ln T$ fit yields a very large uncertainty of J_1 ; therefore no meaningful values of J_1 could be obtained and no clear correlation with the exchange coupling strength calculated from the saturation field (Sec. III) was found. Hence, we exclusively consider the effective $T^{3/2}$ law in the following. From the corresponding fit to the data we obtain the spin wave parameter B and the average ground state magnetic moment $\langle \mu \rangle$.

It is well known²¹ that the spin wave parameter B increases with decreasing thickness of a ferromagnetic film. This can be understood in the following way: From spin wave theory on the basis of the Heisenberg model we know that B is proportional to $D_0^{-3/2}$ and the spinwave stiffness constant, D_0 , is proportional to the exchange energy per atom. In an inhomogeneous system we assume D_0 to scale with the *average* exchange energy per magnetic atom; hence, in an ultrathin film due to the reduced coordination at the interfaces D_0 will be reduced and B enhanced. This argument would therefore predict an enhancement of D_0 by an interlayer exchange coupling of any sign, i.e., a decrease of the spin wave parameter.

In order to study the influence of the interlayer coupling on the parameter B we have to eliminate the influence of thickness variations of the Ni layer within the series of "coupled films" like it was done for the Curie temperature in Sec. IV. We follow the same principle by first measuring $B(t_{Ni})$ for the uncoupled films and use a numerical interpolation to calculate $B(t_{Au}, t_{Ni}=0.73$ nm) for the coupled films. With the same reasoning as before we assume that the variation of B with t_{Ni} , dB/dt_{Ni} , is the same for both series of samples.

The corrected values of the spin wave parameter are plotted versus Au layer thickness in Fig. 4(c) in comparison to the remanence as a measure of the interlayer coupling [Fig. 4(b)] and to the Curie temperature [Fig. 4(a)]. Qualitatively, the correlation of B to m_R is the same as for T_C : minima of the spin wave parameter, i.e., maxima of spin wave stiffness coincide with strongest ferro- (=maximum of m_R) or antiferromagnetic (=minimum of m_R) coupling, maxima of B occur for zero interlayer exchange (e.g., for $t_{Au} \approx 1$ nm and 1.3 nm). This means that both ferromagnetic and antiferromagnetic interlayer coupling stabilize the magnetic order in the multilayer stack against thermal fluctuations.

The same qualitative result was obtained by Keavney *et al.*¹⁴ for Fe/Ag multilayer films. They determined the B parameter (or more precisely, a prefactor, k , which accounts for the interlayer coupling) from the interface hyperfine field in relatively thick Fe layers (>20 ML). Using their numerical analysis¹⁴ we are able to estimate the interlayer coupling constant, J_1 , from the variation amplitude of B and get values around 0.5 erg/cm² for the largest coupling energy density. This result agrees with the value given by theoretical estimates.⁴

Finally we discuss the ground state magnetic moments obtained from the fits to $m_S(T)$ with a $T^{3/2}$ law: by dividing the total saturation moment of the sample for $T \rightarrow 0$ by the total number of Ni atoms which are directly obtained by XFA we determine the average ground state atomic moment $\langle \mu \rangle$. The result is shown in Fig. 4(d) in comparison to the other quantities discussed above. Clear variations are seen and the dependence of $\langle \mu \rangle$ on t_{Au} qualitatively follows the Curie temperature. It is worth mentioning that both quantities have been determined by completely independent measurements in different temperature regimes. Apparently, a ferromagnetic or antiferromagnetic interlayer coupling not only stabilizes the magnetic order at finite temperatures but also enhances

the ground state moments in the itinerant ferromagnet compared to the uncoupled ultrathin layer. The effect of interlayer coupling on ground state moments has been studied theoretically using a tight binding scheme for the Fe/Cr system²² and indeed a correlation between the coupling and the magnetic moments was found. For Ni/Au, however, no calculations of the moments are known and, in particular, first principles calculations are lacking.

The average Ni moment is considerably reduced compared to bulk Ni ($\mu=0.6\mu_B$). This may be a consequence of hybridization of Ni states at the interfaces. A more detailed discussion of this effect in connection with band calculations will be presented elsewhere.

VI. DISCUSSION AND CONCLUSIONS

It has been shown for Ni(111)/Au(111) multilayered films that all the magnetic properties investigated here—remnance, saturation field, Curie temperature, spin wave stiffness and ground state magnetic moments—show pronounced oscillations as a function of the Au interlayer thickness between 3 and 12 ML. These observations confirm the basic idea that in a metallic multilayer film consisting of ferromagnetic layers separated by nonmagnetic interlayers all magnetic properties should reflect the interference of electron waves which are produced by multiple spin-dependent reflections at the interfaces.

The oscillations observed for the different quantities agree in their wavelength and their phase within the uncertainty of the present experiments. The coupling strength determined from the different properties, however, differ substantially. Several circumstances might account for this fact:

(i) The respective properties are measured at quite different temperatures ranging from $T \rightarrow 0$ up to T_C . The interlayer coupling constant itself is known to vary with temperature; this has been found experimentally^{23,24} and studied theoretically from the standpoint of the Fermi–Dirac statistics of the electrons^{4,25} as well as in relation to spin wave interactions,²⁶ however, no data are available in the literature which refer to the Ni/Au system.

In particular, our data show that the interlayer exchange coupling does not vanish when the critical temperature of the interlayer ferromagnetic order is approached. This is not *a priori* evident and merits further theoretical work.

If J_1 varies with temperature then the spin wave parameter, B , of a coupled multilayer will also depend on temperature. This is not compatible with the established methods of measuring B because they assume B to be constant in a finite temperature range. For a quantitative comparison with more elaborate theories a different fitting scheme will have to be employed.

(ii) In a strongly simplified model we have assumed that all the oscillatory quantities are uniform within each layer in our films. This is not realistic; instead, it is certain that neither the ground state moments nor the spin deviation by spin waves and the interlayer exchange coupling are homogeneous in the perpendicular direction within the individual Ni layers. We indeed measure average values by our magnetometric technique as pointed out earlier. In addition, we have to expect lateral inhomogeneities like different grain orientations, layer thickness fluctuations and roughness. All these deviations from uniformity will affect the different magnetic properties in a different way, the individual components having different weight in the respective physical averaging process. This is probably the main reason for the extremely large values of the exchange coupling energy determined from variations of T_C compared to the oscillations of the saturation field: a cancellation of ferro- and antiferromagnetically coupled regions does not take place with respect to the Curie temperature, but for the remnance and (partially) for the saturation field. Apparently, the influence of local maxima of $|J_1|$ on T_C is very strong but weaker on B and very small on the saturation field.

It would be helpful to measure depth profiles of the magnetic moments and spin wave parameter by using Mössbauer spectroscopy with probe layers. However, this method is practically restricted to Fe and not applicable to Ni; T_C of Fe, on the other hand, is so high that its variation with interlayer coupling could only be studied on superlattices with 1 monolayer Fe films between Au layers.

As a consequence of the arguments given above similar experiments will be carried out on epitaxially grown films with controlled flatness and better structural uniformity. It is expected that this will allow a more quantitative study of the phenomena discussed in this communication, in particular the oscillations of the Curie temperature observed for the first time. Complementary efforts will be made to use a more comprehensive theory of thermal spin waves and phase transitions as well as band calculations for the ground state magnetic moments in exchange coupled multilayer films.

The induced complete position-dependent magnetization density of the copper spacer layer is calculated for Co/Cu(001), as modeled by a Co/Cu₉/Co slab. This density is then analyzed in terms of Friedel oscillations. It is found that the variation of the density is well described by two periods, 1.2 and 1.6 monolayers, which are the nonaliased versions of the RKKY periods found in the interlayer coupling. The induced Cu magnetization is not well described in terms of local Cu moments, arising from local exchange interactions, but rather has significant free electron character, in the way that it is mainly induced by magnetic interface scattering. © 1996 American Institute of Physics. [S0021-8979(96)48308-2]

I. INTRODUCTION

The magnetic interlayer coupling through nonmagnetic spacer layers has attracted a huge interest in recent years mainly because of potential applications of the related giant magnetoresistivity (GMR). Until now, the induced magnetization in the spacer layer has been largely neglected, in part because its direct contribution to the coupling may be very small. There have, however, been some recent experimental attempts to measure the magnetization distribution within a copper spacer layer.¹⁻³ Since the induced local magnetic moments are so much smaller than those of the magnetically ordered layers, these attempts have only achieved partial success. Also first principles calculations have obtained local magnetic moments of the atoms within the spacer layer.⁴ These small magnetic moments typically vary both in magnitude and sign as a function of the distance from the magnetic layer. Due to restrictions on spacer-layer thickness imposed by present-day computers, there are usually not enough independent calculated magnetic moments to get full information on the functional form of these oscillations. In this paper we present density functional based calculations of the full magnetization density for Co/Cu(001) systems. The calculated density, as opposed to the local magnetic moments, is then analyzed in terms of Friedel oscillations.⁵

II. METHOD

The calculations have been performed with the linearized augmented plane wave (LAPW) method within the local spin density approximation. The calculations were self-consistent and no shape approximations to the densities or potentials were made. The systems studied were based on a fcc crystal with the copper lattice constant and consisted of Co/Cu₉/Co units separated by an empty gap of three atomic layers. This structure permits both a ferromagnetic (F) and antiferromagnetic (AF) alignment of the magnetic moments of the two cobalt layers within one unit. The Brillouin zone integrations were performed with a dense two-dimensional mesh of special **k** points, 528 points in the irreducible part.

III. RESULTS

In Fig. 1 the induced density $m(\mathbf{r})$ for the F case is shown for a slice in the (100) plane which goes through atoms of all the different atomic layers of the spacer layer [$m(\mathbf{r})/|m(\mathbf{r})|^{1/2}$ is plotted in order to bring out the small features]. Due to the inversion symmetry present when the magnetic layers are F aligned, there are only five independent spacer-layer atoms, and the plot is therefore only over half the spacer layer. The atoms are situated at those places where the density has most structure. The local magnetic moments deduced from this magnetization density are in good agreement with other studies, with a relatively large moment (here $0.006 \mu_B$) at the first Cu layer parallel aligned to the Co moments and smaller ones of varying sign at larger distances. From this figure one can deduce that the magnetization is oscillatory and decaying when going away from the magnetic layer.

The oscillatory behavior may be viewed as arising from the spin-dependent interference of spacer-layer Bloch waves with the waves reflected at the interface with the magnetic layer. This behavior is generally known as Friedel oscillations.⁵ It can be shown that in a generalization to realistic cases this induced magnetization satisfy,⁶

FIG. 1. The magnetization density within the spacer layer is plotted in the form $m/|m|^{1/2}$ for a slice in the (100) plane. The slice is chosen so it goes through atoms of each atomic layer within one half of the spacer layer.

$$m(\mathbf{r}) = \sum_i \frac{A_i}{z^2} |\psi(\mathbf{k}_i, \mathbf{r})|^2 \cos(\Delta k_i z + \phi_i), \quad (1)$$

for an asymptotically large distance from the magnetic layer. Here z is the distance to the interface, the sum is over the stationary Fermi surface calipers Δk_i , well-known from RKKY theory,⁷ A_i and ϕ_i are, respectively, the amplitude and phase of the i th oscillation, and ψ is the Block wave function corresponding to an end-point \mathbf{k}_i of the i th caliper. The space dependent weighting factors $|\psi|^2$ are the cause of the structures in the magnetization density centered at the spacer-layer atoms in Fig. 1. These make the interpretation of the magnetization density nontrivial.

In order to make an analysis of the magnetization density possible in terms of the expression in Eq. (1) without assuming any prior knowledge of Fermi surface calipers or the corresponding amplitude, an approximation that $\psi(\mathbf{k}, \mathbf{r})$ is independent of the specific Fermi surface wave vector has to be made. Further, this Fermi-surface-averaged $|\psi|^2$ is assumed to be proportional to the magnetization density $m_0(\mathbf{r})$ of pure fcc Cu obtained in a calculation with a small external magnetic field. This assumption should be valid for a small enough field strength, here we have used a field giving rise to a magnetic moment of $10^{-4} \mu_B$. With the above assumptions, the dimensionless quantity $\mu = (z/a)^2 m/m_0$, where a is the lattice constant, should be a superposition of pure oscillations as a function of z for large distances from the interface

$$\mu(\mathbf{r}) = \sum_i B_i \cos(2\pi z/\lambda_i + \phi_i), \quad (2)$$

where $\lambda_i = 2\pi/\Delta k_i$ is the RKKY wavelength and B_i is the new amplitude. Although the normalization with m_0 takes away a large part of the atomic-like structure in Fig. 1, some unwanted features remain due to the approximations involved in this procedure. In order to get rid of this remaining noise, and at the same time to get down to only one variable $\mu(\mathbf{r})$ is also integrated over the plane perpendicular to z ,

$$\tilde{\mu}(z) = \int dx dy \mu(x, y, z). \quad (3)$$

In our systems there is more than one interface and each causes Friedel oscillations. By adding the two different magnetization densities calculated with F and AF ordering, the contribution from the second interface may be largely canceled. In Fig. 2 the resulting renormalized magnetization density $(\tilde{\mu}_F + \tilde{\mu}_{AF})/2$ has been plotted. There are clearly smooth oscillations throughout the spacer with an effective period just above one monolayer (ML). However, these oscillations are not centered around zero; they are below zero for distances shorter than 5 ML and above for larger distances.

As is well known from RKKY theory for the case of fcc Cu(001) there are two Fermi surface calipers contributing to the oscillations of Eq. (2). A fit to two independent oscillation periods finds 1.58 and 1.28 ML with the amplitude of the latter three times larger than that of the former. The resulting curve is also plotted in Fig. 2. While the fit becomes better the further away the fitting interval is taken from the

FIG. 2. The sum of the ferromagnetic and antiferromagnetic induced magnetization density in the form given by Eq. (3), is plotted for the spacer layer (full curve). The distance is with respect to the closest Co atom in units of monolayers (ML). Fits of this curve to the form in Eq. (2) when using two (diamonds) and three (dashed curve) independent oscillations are also shown.

magnetic layer, a fair asymptotic limit is already reached at 3.5 ML. The fast oscillations are well reproduced with this fit, but it fails to mimic the apparent long wavelength feature of the negative and positive offsets. This is probably because the latter is not of oscillatory nature but is caused by the finite size of the spacer layer used in the calculation. The magnetization density in our calculation has not only to fulfill the boundary condition at the interface as the “true” Friedel oscillation, but is in addition forced to be symmetric (F) or antisymmetric (AF) around the central fifth atom in the spacer layer. In the present case, the AF solution has taken a somewhat peculiar form in order to fulfill this latter condition. This results in the steplike feature at 5 ML. A better fit to the curve is obtained when allowing for three oscillations, the result of which is also shown in Fig. 2. The third period becomes just above 5 ML in order to reproduce the step.

The two physical periods are very close to what is expected from the two calipers of the “dog-bone” of the Cu Fermi surface, 1.2 and 1.6 ML. These periods correspond to 5.9 and 2.6 ML, respectively, when they are sampled on the discrete lattice as when studying atomic moments or interlayer coupling,⁸ i.e., with the “aliasing effect.”

IV. CONCLUSIONS

As is clear from Eqs. (1) and (2) there is a connection between the Friedel oscillations and the RKKY oscillations of the interlayer coupling. The periods, apart from the aliasing, are identical, and since both phenomena arise from spin-dependent interface reflections the relative strengths of the different oscillations should be related. So in principle, with a calculation for one interlayer distance, which, among all possible RKKY oscillation periods are most important, can be determined. As true Friedel oscillations only exist for asymptotic distances from the interface, a relatively thick spacer layer has to be used in the calculation. But as has been shown, one way to double the effective thickness is to do

FIG. 3. The local magnetic moments within a muffin-tin sphere of radius 2.25 a.u. are plotted against the magnetization density at the corresponding atomic nucleus for all independent atoms of the spacer layer. Both quantities have been multiplied with the squared distance from the interface and the units are arbitrary.

both a F and an AF calculation. In the analysis, besides the pure Friedel oscillations, care is needed to avoid extrinsic features due to the finite interlayer distance.

Another thing to observe is that the rather rapid oscillations found make the concept of local atomic moment in the spacer layer more ambiguous than usual. The magnitude of a local magnetic moment depends on which part of space is ascribed to each atom. Fortunately, reasonable choices of atomic or muffin-tin spheres usually give magnetic moments in fair agreement with each other. However, when there is an oscillation with an effective period of almost atomic dimensions, a change of sphere radii may not only change the magnitude but also the sign of the magnetic moment. In order to illustrate this we chose two quantities related to the atomic part of the magnetization density, the local magnetic

moment within a muffin-tin sphere with radius 2.25 a.u., and the magnetization density at the atomic nucleus, and plotted these, both multiplied with the square of the distance from the interface, against each other for all independent atoms of the F and AF systems (Fig. 3). These two quantities are usually proportional, as in, e.g., a ferromagnet, but here they are all scattered around and not even the sign is consistent. One way to view this is that instead of having local magnetic moments arising from a local exchange mechanism the Cu spacer layer has a more "free electron-like" induced magnetization, in accordance with the fact that it is well described as Friedel oscillations. This also affects interpretations of experimental results as, e.g.,¹⁻³ where the magnetization density is probed close to the nucleus implicitly assuming a sort of local magnetic moment.

In summary, a way to analyze the induced magnetization density within a spacer layer has been presented. When applied to Cu(001) a very good agreement with the expected Friedel oscillations is obtained. The method presented here is quite general and can be applied straight-forwardly to other types of spacer layers as well.

Interface alloying at Fe/Cr interfaces and its role in exchange coupling, angular resolved Auger electron, magneto-optic Kerr effect, and Brillouin light scattering studies (invited)

Angular resolved Auger electron studies were carried out for Fe whisker/Cr(001) interfaces which were prepared at 100, 180, 246, and 296 °C. The Cr atoms penetrate progressively into the second (counting from the surface) atomic layer at 100, 180, and 246 °C. At 296 °C the Cr atoms enter the third atomic layer. No noticeable fraction of the Cr atoms was found in the fourth atomic layer. The exchange coupling was studied in Fe whisker/Cr/Fe(001) films which were grown in a nearly perfect layer by layer mode. Magneto-optic Kerr effect and Brillouin light scattering measurements showed that the measured change in the phase of the short wavelength oscillations, the presence of a slowly varying exchange coupling bias, and the small measured values of exchange coupling are caused by the same mechanism: interface alloying. The exchange coupling in Fe whisker/Cr/*n*Fe specimens, for *n*=10, 20, 30, and 40 ML, showed no obvious dependence on the Fe layer thickness. © 1996 American Institute of Physics. I. INTRODUCTION

Fe whisker/Cr/Fe(001) systems have played a crucial role in the study of exchange coupling between two ferromagnets separated by a nonferromagnetic spacer. The scanning electron microscopy with polarization analysis (SEMPA) studies by the NIST group¹ and the magneto-optic Kerr effect (MOKE) measurements by the Philips group² using Fe whisker/Cr/Fe(001) samples showed that the exchange coupling oscillates with a short wavelength period of ~2 ML. The SEMPA measurements very clearly revealed short wavelength and long wavelength oscillations in the thickness range of 5–80 ML of Cr. The period of the short wavelength oscillations was found to be slightly incommensurate with the Cr lattice spacing, $\lambda=2.11$ ML, the period of the long wavelength oscillations was found to be 12 ML. Short and long wavelength oscillations have been observed also for samples grown on a GaAs(001) substrate covered with a thick buffer layer of Ag(001).³ The SFU group has carried out quantitative studies using Fe whisker/Cr/Fe(001) samples.^{4,5} The objective of the SFU group was to grow samples having the best available interfaces, to measure quantitatively the strength of the exchange coupling, and to compare it with *ab initio* calculations which included explicitly the presence of spin-density waves in Cr.^{6,7} The requirement of smooth interfaces limited the study to samples which were grown on Fe whisker templates with the Cr spacers terminated at an integral number of Cr atomic layers. It was found that the strength of the exchange coupling through the Cr(001) spacer is extremely sensitive to small variations in growth conditions. The measured exchange coupling was found to be reproducible only in those samples that exhibited layer by layer growth. The existence of unattenuated reflection high-energy electron diffraction (RHEED) intensity oscillations of the specular spot during the growth of the Cr spacer did not guarantee reproducible results. The width of the RHEED specular spot profiles had to be monitored and one had to establish conditions such that the atom island

formation followed a prescribed pattern of nucleation and growth. The best results were obtained for the case when the spot profiles oscillated repeatedly between narrow peaks (filled atomic layers) and split intensity peaks (half-filled layers). This was possible to achieve by maintaining the substrate temperature in a narrow range of temperatures, $280^\circ\text{C} < T_{s,\text{opt}} < 320^\circ\text{C}$. The presence of the specular spot splitting for half-filled atomic layers indicated that new atomic layers were formed from nucleation centers which were separated by a well defined mean distance. The mean separation between atomic islands was found to be ~800–900 Å at $T_{s,\text{opt}}$.^{4,5} This interpretation is in agreement with the recent scanning tunneling microscopy (STM) studies by Stroscio.⁸ Samples grown in that way showed unattenuated RHEED intensity oscillations with well defined cusps at the RHEED intensity maxima. The first monolayer of Cr exhibits a unique behavior; the first RHEED intensity oscillation shows a strong peak with a very sharp cusp even at substrate temperatures as low as 150 °C indicating that the first atomic layer grows very smoothly. The situation changes when Cr is deposited on a Cr template. In that case the growth of Cr proceeds layer by layer only if the substrate temperature is adjusted to an optimum growth temperature, $T_{s,\text{opt}}$.

Quantitative Brillouin light scattering (BLS) studies have clearly exhibited short wavelength oscillations in the exchange coupling.^{4,5} These studies showed also for the first time that the exchange coupling through Cr(001) contains both oscillatory bilinear, J_1 , and positive biquadratic, J_2 , exchange coupling terms. The exchange energy is given by

$$E = -J_1 \cos(\theta) + J_2 \cos^2(\theta),$$

where θ is the angle between magnetic moments of the ferromagnetic layers. The thickness dependence of J_1 in Cr exhibits several interesting features. Firstly, for a Cr spacer which is thinner than 8 ML the strength of the short wavelength oscillations is quite weak, $|J_1| \sim 0.1$ ergs/cm². The exchange coupling in this range is antiferromagnetic only due to the presence of an antiferromagnetic (AF) long-wavelength bias. The coupling crosses over to ferromagnetic (FM) coupling for thicknesses less than 3 ML. The AF bias is peaked around 4 ML and dies out gradually as the thickness

^{a)}Permanent address: Dept. of Physics and Astronomy, McMaster Univ., Hamilton, Ontario, Canada.

approaches 9 ML. It is interesting to note that the strength of the AF bias is very nearly the same as that observed in Fe/Cr/Fe(001) epitaxial multilayers prepared by sputtering where the interface roughness has annihilated the presence of the short wavelength oscillations.⁹ For a Cr spacer thicker than 8 ML, $d_{\text{Cr}} > 8$ ML, the exchange coupling is dominated by the short-wavelength oscillations. In this thickness range the samples are strongly antiferromagnetically coupled, $J_{\text{tot}} = |J_1 - 2J_2| \sim 1.0 - 1.5$ ergs/cm², for an odd number of Cr atomic layers and weakly ferromagnetically (FM) coupled for an even number of Cr atomic layers, $J_{\text{tot}} \sim 0.01 - 0.1$ ergs/cm². The thin film peak position in the BLS spectra for FM coupled samples is right at the threshold of the bulk Fe (whisker) spin manifold. This asymmetric behavior in J_{tot} can be explained by the presence of the biquadratic exchange coupling, J_2 . The total exchange coupling through the Cr spacer for the parallel orientation of the magnetic moments is given by $J_{\text{tot}} = J_1 - 2J_2$, and therefore the biquadratic exchange, $J_2 > 0$, increases the strength of AF coupling, and decreases the strength of FM coupling. The observed weak FM coupling implies that $J_1 \sim 2J_2$. The biquadratic coupling J_2 was found to be approximately 0.25 ergs/cm² and this leads to a bilinear exchange coupling strength of $J_1 = 0.5$ ergs/cm² for FM coupled samples. This strength of J_1 is close to that found for AF coupled samples; and therefore an apparent weak FM coupling in Cr is more the consequence of a strong J_2 , than the result of a weak intrinsic FM bilinear coupling J_1 .

The coupling between the Fe and Cr atoms at the Fe/Cr interface is expected to be strongly antiferromagnetic^{10,11} and in consequence the spin density wave in Cr is locked to the orientation of the Fe magnetic moments. Since the period of the short wavelength oscillations is close to 2 ML one expects AF coupling for an even number of Cr atomic layers and FM coupling for an odd number of Cr atomic layers. For the period of $\lambda = 2.11$ ML the first phase slip in the short wavelength coupling is predicted to occur at 24 ML. Surprisingly, the SEMPA¹² and BLS¹³ measurements showed that the phase of the short-wavelength oscillations is exactly opposite to that expected. It is also important to note that the strength of the exchange coupling $|J_{\text{max}}| \sim 1.0$ ergs/cm², was found to be much less than that obtained from the first principal calculations, $|J_1| = 30$ ergs/cm².⁶ This represents a significant disagreement between experiment and theory. Since Fe whisker/Cr/Fe(001) samples can be prepared in a nearly perfect layer by layer growth, the above disagreement between the measured exchange coupling and the theoretical calculations cannot be *a priori* blamed on poor sample quality. The possibility that the theoretical calculations provide too great a strength for the exchange coupling is not entirely out of the question, but the reversed phase of the short wavelength exchange coupling is rather hard to accept in the light of two facts: (a) Cr metal is known to possess an intrinsic short wavelength spin density wave, and (b) the coupling between Fe and Cr atoms is known to be strongly antiferromagnetic. Therefore, one should entertain the possibility that the above discrepancies between theory and experiment are caused by sample structural features.

Our recent studies showed that the strength of the bilin-

FIG. 1. (a) Experimental configuration for angular resolved Auger electron spectroscopy (ARAES) measurements. **a** is the line of acceptance of Auger electrons, and the incident electron beam (2.0 keV) is directed along the line **e**. The angle between **a** and **e** is 54°, and **n** is the sample surface normal. The drawing shows the configuration for $\Theta = 0^\circ$, **n** parallel to **a**. Angular resolved studies were carried out varying the polar angle Θ (measured from **n**). The azimuthal angle Φ was used to select an appropriate lattice plane for the ARAES measurements. (b): An illustration of rows of atoms in the bcc (011) crystallographic plane ($\Phi = 45^\circ$) which dominantly contribute to forward scattering of Auger electrons, see details in the text.

ear exchange coupling J_1 is very sensitive to the initial growth conditions. The bilinear exchange coupling can be changed by as much as a factor of 5 by varying the substrate temperature during the growth of the first Cr atomic layer. On the contrary, the strength of the biquadratic exchange coupling was found to be quite insensitive to the initial growth conditions. This is a surprising result considering that the first RHEED intensity oscillation, corresponding to the first Cr atomic layer, usually shows a large oscillatory amplitude with a sharp cuspy maximum even at relatively low substrate temperatures, $T \sim 150^\circ\text{C}$, and therefore it was expected that a perfect formation (no pile-up of Cr atoms) of the first Cr atomic layer would not negatively affect the subsequent growth. The sensitivity of J_1 to the initial growth conditions has led us to believe that the atomic formation of the Cr layer is more complex than has been so far acknowledged. In the following we will demonstrate by using angular resolved Auger electron spectroscopy (ARAES) that atomic interface alloying at the Fe whisker/Cr interface due to an atom interface exchange mechanism plays a very significant role and strongly affects the exchange coupling through the Cr spacer.

II. GROWTH AND ARAES STUDIES

The angular distribution of the Cr KVV Auger electrons (529 eV) was used to investigate interface alloying in the Fe whisker/Cr(001) interface. Auger electrons having an energy of several hundred eV energy are strongly forward scattered in the directions interconnecting the emitter with its nearest and next nearest neighbors. This forward scattering is strongest when the effect is limited to single scattering events;¹⁴⁻¹⁶ i.e., when the ARAES measurements are limited to a few MLs. The experimental configuration in our ARAES studies is shown in Fig. 1. The ARAES studies were carried

out using an uncommon whisker blade, $100 \times 500 \times 10^4 \mu\text{m}$, with the [001] axis along its long edge and with the large facets oriented in {001} planes. The Fe whisker was mounted on an ultrahigh vacuum (UHV) goniometer equipped with polar, Θ , and azimuthal, Φ , rotational degrees of freedom. The line of acceptance of Auger electrons, **a**, to an OMNI lens of the hemispherical analyzer, PHI-10-360 (2° angle of acceptance with the focal area of $\phi=500 \mu\text{m}$ in diameter), and the normal to the sample, **n**, are perpendicular to the polar axis, Θ , of our UHV goniometer. In our ARAES studies the Fe whisker was initially oriented with its (011) crystallographic plane perpendicular to Θ corresponding to the azimuthal angle $\Phi=45^\circ$. The incident electron beam (2 keV), **e**, lies in the plane formed by the polar axis Θ and **a**. The angular dependence of the LVV Cr and Fe Auger peaks was measured by rotating the sample, using the polar angle Θ of our UHV goniometer, thus all atomic rows lying in the (011) plane were available to the input of the Auger analyzer. In this configuration the Auger electrons originating from the top surface layer have a flat angular dependence. The atoms in the second, third, and fourth atomic layers have their Auger peaks enhanced for the polar angle $\Theta=54.7^\circ$ (along the body diagonal [111]), the third and fourth atomic layers have their Auger peaks also enhanced along $\Theta=0^\circ$ (along the cube edge [001]), and the fourth layer is also enhanced for 25.2° (along the [1,1,3] direction, see Fig. 1). Thus the Cr occupation of the individual atomic layers near the surface can be determined by measuring the polar angular dependence of the Cr LVV (529 eV) Auger peak. The orientation of the incident electron beam, **e**, in our system leads to a more complex behavior when the Auger signal is measured along the [001] axis. For $\Theta=0^\circ$ the impinging electron beam is nearly parallel to the body diagonal. In this case the flux of impinging electrons is significantly enhanced for those atoms that are located in the first and second atomic layer below the surface. The effect is caused by the forward focusing due to the row of atoms along the body diagonal. In that case, the maximum around $\Theta=0^\circ$ could be incorrectly interpreted as evidence for the presence of Cr atoms in the third layer. This spurious effect was eliminated by rotating the azimuth Φ of the sample away from 45° to 34.5° . The 45° azimuth was perfectly suitable for measurements made off the sample normal, $\theta > 10^\circ$, where the forward focusing effect is absent.

The goal of our ARAES measurements was to identify the level of interface Fe–Cr alloying. For this purpose we deposited 0.5 ML of Cr at various substrate temperatures, and carried out appropriate ARAES using the Cr LVV Auger peak. The results of our studies are shown in Fig. 2, where the ARAES data are shown for substrate temperatures, $T_{\text{sub}}=180, 246$, and 296°C . Further details of this work can be found in Ref. 17. Figures 2(b) and 2(d) show no maximum around $\theta=0^\circ$, but a clear maximum is visible for $\theta=54^\circ$ in Figs. 2(a) and 2(c). Figures 2(e) and 2(f) show maxima for both angles. The presence of these maxima clearly indicates that interface mixing is present during the growth of Cr on Fe whisker substrates. At 180°C the Cr atoms only penetrate into the second atomic layer. At 296°C the Cr atoms even enter the third atomic layer. No peak is evident along 25° indicating that for this range of substrate

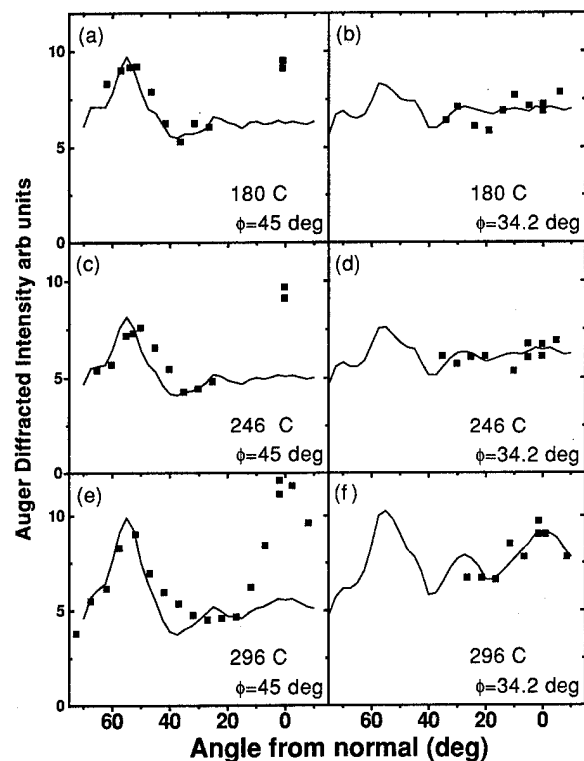

FIG. 2. Polar angular dependence of the LVV Cr Auger electron peak from a 0.5 ML thick Cr layer deposited on an Fe(001) whisker blade. The deposition of Cr was carried out at the substrate temperatures of 180° , 246° and 296°C , respectively. The peaks around $\Theta=0^\circ$ for the azimuth $\Phi=45^\circ$ are caused by forward focusing effect of the incident electron beam, see the text. The solid lines are fits using the computer program SSC,¹⁶ see the text.

temperatures the Cr ad atoms do not penetrate into the fourth atomic layer. The measured ARAES data were analyzed using the computer program SSC developed by Fadley and his co-workers.¹⁶ The scattering is treated using scattering phase shifts from the computer program FEFF-3 developed by Rehr and his co-workers.¹⁸ The single scattering approach is fully justifiable for Cr atoms distributed in the first two atomic layers. For atoms in the third atomic layer the single scattering approach is not fully adequate for $\theta=54^\circ$. In that case the Auger electrons propagate along two atoms in the body diagonal where the effect of multiple scattering is not negligible. Calculations along the close packed directions show that the effect of multiple scattering is equivalent to the reduction of the intensity of the Auger electrons to 60% of its value calculated using the single scattering approach.¹⁶ The results of our analyses are summarized in Table I. Table I shows that interface alloying plays a role even at low substrate temperatures and becomes very significant at substrate temperatures for which a thick Cr spacer can be grown in the layer by layer mode.

One should point out that interface alloying is an asymmetric effect; it happens only at one interface.¹⁹ Interface alloying is driven by the difference in binding energies between the substrate and ad atoms. The binding energy is proportional to the melting point of the appropriate solids. Interface alloying has been observed in systems for which the substrates have lower melting points than those of the ad

TABLE I. Fractions of the Cr atoms in the first (surface layer), second and third atomic layers obtained from SSC fits (Ref. 16). A half ML of Cr was grown on an Fe(001) whisker template at 100, 180, 246, and 296 °C. The use of a third layer in SSC calculations for samples prepared at 100, 180, and 246 °C provide better overall fits around $\Theta=0^\circ$, but the measured angular variations around $\Theta=0^\circ$ are on the border line of our experimental accuracy, and therefore the fractions determined in the fourth column might well be incorporated into the second layer (shown in brackets in the third column).

Temp [°C]	First	Second	Third
100	0.82	0.13(0.18)	0.05
180	0.74	0.21(0.26)	0.05
246	0.67	0.30(0.33)	0.03
296	0.51	0.30	0.19

atom solids.^{19,20} The melting point of Fe (1808 K) is lower than the melting point of Cr (2130 K), and thus the condition for interface alloying is satisfied.

Cr and Fe form miscible alloys. At this point it is fair to ask whether the substrate Fe atoms are involved in surface segregation at the top of the Cr spacer. To investigate this point an 11 ML Cr film was grown and then the Fe LVV peak intensity was compared to that with no Cr coverage. It was found that the Fe Auger signal decreased by 8.8-fold. Since the Auger signal was collected perpendicular to the surface this decrease is caused by two factors: (a) The removal of the forward scattering enhancement due to the presence of the 11 ML thick Cr layer. (b) The attenuation of the Fe Auger signal due to the propagation through the 11 ML thick Cr. The first factor decreases the signal by 2.5 times, the second factor can be estimated using the formula for the electron inelastic mean free path 1. For the Fe LVV Auger electrons (729 eV) in Cr. $l=12 \text{ \AA}$,²¹ and results in an attenuation of 3.7 times. The total expected attenuation is 9.3 times, this is very close to the observed attenuation of 8.8 times. Therefore there is no evidence that the interface alloy mixing goes beyond the first Fe/Cr interface. The ARAES measurements were always carried out for both the Fe whisker template and the Cr overlayers. By integrating the Cr and Fe Auger intensities between $\Theta=0^\circ$ to 60° one can obtain a good estimate for an effective Cr coverage as seen by the Auger analyzer. The reference point used in this calculation was the total Fe AES signal. Using a simple formula which includes the appropriate Auger atomic sensitivities²² and the Fe Auger electron mean free path in the bulk Fe results in an effective Cr coverage of 0.8 ML. This is somewhat bigger than that predicted by the RHEED intensity oscillations, 0.5 ML. Considering that the Fe Auger signal involves at least 10 atomic layers, where the contribution of electron multiple scattering is non-negligible, the above estimate of an effective Cr coverage is very reasonable. The Cr atoms were confined to the vicinity of the Fe whisker surface.

III. MAGNETIC STUDIES AND DISCUSSION OF RESULTS

The exchange coupling through Cr is most likely affected by interface alloying. This point was verified by using two Fe whisker/11Cr/20Fe(001) samples. In the first sample the Fe/Cr interface was formed at $T_s=180^\circ\text{C}$ and then the

rest of the Cr spacer was grown with T_s at 250°C and 300°C to maintain a good layer by layer growth at higher Cr coverages. The second sample was grown starting at a substrate temperature $T_s=244^\circ\text{C}$. and then the last 4 ML were grown at $T_s=294^\circ\text{C}$. The MOKE and BLS measurements exhibited two critical fields. For fields $H>H_2$ the magnetic moments in the Fe whisker and in the ultrathin film were clearly parallel to the applied external field, the sample was fully saturated, and no gradual approach to saturation was observed. For $H<H_2$ the magnetic moments were noncollinear, the magnetic moments deviated from the external field direction. The antiferromagnetic configuration was reached for fields $H<H_1$, where H_1 is the lower critical field. The existence of a fully saturated state for fields $H>H_2$ is consistent with the assumption that the angular variation of the exchange coupling is expressed in terms of bilinear and biquadratic exchange coupling. The positions of critical fields H_1 and H_2 were used to calculate J_1 and J_2 using a micro-magnetic calculation for an Fe whisker/Cr/20Fe sample.²³ The results of these calculations showed that the exchange coupling depended very strongly on interface alloying. The sample with the Fe/Cr interface prepared at a lower substrate temperature, $T_s=180^\circ\text{C}$, exhibited a much larger bilinear exchange coupling, $J_1=-1.23 \text{ ergs/cm}^2$, than the specimen having an Fe/Cr interface prepared at a higher substrate temperature, $T_s=244^\circ\text{C}$ (-0.4 ergs/cm^2). For $T_s=180^\circ\text{C}$ two samples were grown; in the second sample the Cr spacer was 10 ML thick. This sample was strongly coupled ferromagnetically so that the thin film peak was sufficiently shifted in frequency that it disappeared into the spin-wave manifold of the Fe whisker. This result is a consequence of a large positive J_1 . Since J_2 is weakly dependent on the substrate temperature the effective total FM coupling, J_1-2J_2 , increased substantially.

Stoeffler and Gautier have shown that the presence of Fe in Cr atomic layers around the interfaces affects the magnetic behavior. The Cr atoms at the interface are subjected to conflicting exchange coupling requirements due to the particular geometrical configuration of their neighbors. The orientation of the Cr atomic moments is magnetically frustrated by the lack of a sharply defined chemical environment. Stoeffler and Gautier showed²⁴ that an interface composed of two ordered {Fe(75%)–Cr(25%), Cr(75%)–Fe(25%)} atomic layers already shows a sufficient level of magnetic frustrations to change the phase of the coupling and to substantially decrease J_1 . The magnetic moment of the mixed Cr layer (75%Cr–25%Fe) was found to be parallel to the adjacent Fe magnetic layer. It is the second Cr atomic layer which has its magnetic moment oriented antiparallel to the Fe layer. The magnetic moments in the subsequent Cr atomic layers oscillate between parallel and antiparallel configurations. Since this effect is only confined to one interface the phase of the exchange coupling through Cr(001) is reversed from that expected for an ideal interface. Magnetically speaking the Cr spacer lost one atomic layer. The parity is changed, an odd number of Cr atomic layers becomes an even number and vice versa. The calculated strength of the short wavelength coupling in the sample with intermixed interfaces was found to be close to that obtained in our measurements. It is also

FIG. 3. (a) MOKE signal for the Fe whisker/11Cr/30Fe/20Au(001), thicknesses are measured in ML. The curve has asymmetric features which are most likely associated with the magnetization component transversal to the external field H^{25} (b) A symmetrized hysteresis loop. The contribution of the transversal component has been removed by subtracting the measured MOKE data for positive and negative fields; $M(H) = [M(H) - M(-H)]/2$. The upper and lower curves correspond to decreasing and increasing fields, respectively.

interesting to point out that the magnetic frustrations in their calculations led to AF coupling for $d_{Cr} < 4$ ML and resulted in a FM bias between 4 and 10 ML of Cr. Our measurements showed FM coupling up to 3 ML and a slowly varying AF background between 4 and 9 ML of Cr. The slowly varying background in the measured exchange coupling has the same thickness variations as the above calculations, but the phase is reversed. The calculations were carried out for the symmetric case. In our samples the magnetic frustrations occur at one interface only. The Cr moment distribution at the alloyed interface²⁴ suggests that for the thicknesses between 1 and 4 ML of Cr the coupling changes to FM and that results again in the reversal of the phase. The level of interface alloying in our samples is comparable to that used in the Stoeffer, Gautier calculations, and therefore we believe that the following statement can be accepted with a reasonable degree of credibility: The measured change in the phase of the short wavelength oscillations, the presence of a slowly varying exchange coupling bias and the small measured values of exchange coupling are caused by the same mechanism, namely interface alloying.

Ab initio tight binding calculations predict that the coupling through Cr should be only weakly dependent on the thickness of Fe layers when the thickness of the Fe layers is more than several ML. This result is a direct consequence of the presence of spin density waves in Cr and the Heisenberg like nature of the exchange interactions in Fe/Cr.⁶ We prepared four samples with thicknesses of 10, 20, 30, and 40 ML of Fe to investigate this point. The samples were grown on the same Fe whisker using a shutter during the growth of the Fe layer. The same Cr thickness of 11 ML was used for all samples. The first four atomic layers of Cr were grown at $T_s = 180^\circ\text{C}$ to decrease the interface alloying. Quantitative measurements were carried out using MOKE (longitudinal Kerr effect) and BLS. A typical hysteresis loop is shown in Fig. 3(a): It clearly shows a well defined saturation field H_2 and a jump in the total magnetic moment when the Fe film magnetic moment becomes oriented antiparallel to the Fe whisker magnetic moment. The measured magnetization

loops show a certain degree of hysteresis and also an asymmetric behavior for positive and negative fields. The asymmetry could be caused by the component of the magnetic moment transverse to the field for $H_1 < H < H_2$, as described recently by Osgood *et al.*²⁵ In order to eliminate the role of the transversal magnetic component in our measurements the data for negative and positive fields were subtracted. The subtraction was carried out for decreasing fields [lower curve in Fig. 3(b)] and for increasing fields [upper curve in Fig. 3(b)]. This procedure resulted in a symmetric curve as expected, Fig. 3(b). The measured magnetization curves were fit using a full micromagnetic calculation. The results of the analysis, shown in Table II, clearly indicate that the coupling through Cr is independent of the Fe thickness. Only a small decrease (10%) was found in the total exchange coupling, $|J_1 - 2J_2|$, for the 10 ML thick sample. However in this case the upper field H_2 as measured by MOKE (~ 7 kOe) was almost at the upper limit of our magnet, and therefore the difference in the strength of the coupling could have been due to underestimating H_2 .

BLS measurements were carried out on the same sample. The AF coupling led to a well defined thin film peak. The BLS spectrum for the 30 ML thick sample is shown in Fig. 4. The data are characterized by two well defined fields

TABLE II. The bilinear, J_1 and biquadratic, J_2 , exchange couplings as determined from the BLS and MOKE measurements. The coupling is in ergs/cm² and the Fe thickness, d , is in ML. The MOKE results were obtained using the critical fields H_1 , H_2 , see Fig. 3. The BLS results were obtained by fitting the measured field dependence of the Fe film resonance peak, see Fig. 4.

d	BLS		MOKE	
	$-J_1$	J_2	$-J_1$	J_2
10	0.74	0.23	1.0	0.25
20	1.02	0.23	1.1	0.33
30	0.96	0.23	1.15	0.31
40	0.95	0.23	1.08	0.34

FIG. 4. Frequency vs applied magnetic field for the whisker/11Cr/30Fe/20Au specimen (thicknesses are in ML). Frequencies were measured using BLS in the backscattering configuration and 0.5145 μm laser light incident at 45°. The solid lines were calculated using $4\pi M_s = 21.44$ kOe, $K_1 = 4.76 \times 10^5$ ergs/cm³, and $g = 2.09$ for both bulk iron and the 30 ML thin film. We used uniaxial surface energy parameter $K_{\text{MA}} = 1.0$ ergs/cm² (0.5 ergs/cm² at each surface)²⁶ which is in agreement with our recent measurements of the surface anisotropy on Ag/Cr/Fe/Au(001) samples. The exchange stiffness $A = 2.03 \times 10^{-6}$ ergs/cm. The exchange coupling parameters were $J_1 = -0.96$ ergs/cm² and $J_2 = 0.23$ ergs/cm². Micromagnetic calculations using these values gave lower and upper critical fields $H_1 = 0.77$ kOe and $H_2 = 2.49$ kOe. Note the large frequency splitting between up-shifted frequencies Δ and down shifted frequencies \diamond for fields lower than H_1 where the magnetic moments are antiparallel.

H_1 and H_2 (the lower field H_1 is defined by the sudden change in the frequency splitting between up and down shifted thin film frequencies). The fields H_1 and H_2 were used to determine J_1 and J_2 . The results of these analyses are shown in Table II. The MOKE and BLS results for J_1 and J_2 are similar, but the BLS results are consistently smaller than the MOKE results. By comparing Figs. 3 and 4 it is clear that the saturation fields H_2 are not in agreement. In fact, the saturation fields, H_2 , measured using MOKE are greater by ~ 0.8 – 0.9 kOe compared with those using BLS. The fields H_1 measured using both techniques are in agreement. The values of J_1 and J_2 , determined from the BLS analysis, together with the known magnetic anisotropies of the Fe whisker and the Fe film were used to fit the field dependence of the Fe film resonance frequency. Figure 4 shows that this fit is nearly perfect. This indicates very clearly that the position of the upper cusp in the BLS measurements correctly determines the saturation field H_2 for the Fe film. The discrepancy with the saturation field H_2 measured using MOKE indicates that the BLS and MOKE techniques do not follow exactly the same features of the magnetization loops. No difference between MOKE and BLS measurements was found for samples with simple metallic spacers such as Cu and Ag.⁵ It is therefore very likely that the above discrepancy is related to the Fe whisker/Cr system.

IV. CONCLUSIONS

The above ARAES studies showed unambiguously that interface atom alloying is present in the growth of Cr on

Fe(001). It has been shown that the relatively small measured values for the bilinear coupling, the reversed phase of the short wavelength oscillations compared to those predicted by *ab initio* calculations, and the presence of a slowly varying exchange coupling bias are most likely caused by interface alloying. The dependence of the strength of the exchange coupling on the Fe film thickness was found to be negligible as predicted by *ab initio* calculations.

We present the effects of antiferromagnetic (AF) order of the Cr spacers in Fe/Cr(001) superlattices on the interlayer coupling of the Fe layers. AF order of the Cr spacers is suppressed for layer thicknesses less than 42 Å. For >42 Å of Cr, the Néel temperature (T_N) increases rapidly and asymptotically approaches the bulk value for thick Cr spacers as characterized by a transition-temperature shift exponent $\lambda = 1.4 \pm 0.3$. Neutron diffraction confirms both the AF order of the Cr layers in superlattices with 62, 100, and 200 Å thick Cr layers, and the existence of the incommensurate, transverse spin-density-wave magnetic structure whose nesting wave vector is equal to that of bulk Cr. The AF ordering of the Cr results in anomalies in a variety of magnetic properties, including the interlayer coupling, remanent magnetization, coercivity, and magnetoresistance. Most strikingly, the 90° or “biquadratic” coupling of the Fe layers observed for $T > T_N$ is suppressed below T_N as confirmed by polarized neutron reflectivity. This behavior can be understood in terms of the combination of finite-size and spin frustration effects at rough Fe/Cr interfaces. © 1996 American Institute of Physics. [S0021-8979(96)58608-9]

Trilayers of CoFe/Mn/CoFe(001) have been prepared by molecular beam epitaxy and their magnetic properties measured by magnetometry and ferromagnetic resonance. Very strong near-90° coupling between the CoFe layers, with no evidence for 180° coupling, was found in all but the thickest Mn-layer samples. The coupling energy has the form suggested recently for the case when the interlayer itself is antiferromagnetic. An analysis of the ferromagnetic resonance data indicates that the magnitude of the coupling oscillates with the Mn thickness. © 1996 American Institute of Physics. [S0021-8979(96)48508-5]

In this paper, we present experimental results on single crystal epitaxial sandwich samples of CoFe/Mn/CoFe. These samples exhibit the largest near-90° type magnetic layer coupling ever observed and are without any detectable bilinear coupling.¹ The actual form of the coupling is consistent with a recent theoretical model based upon the intervening layer being antiferromagnetic.² In this work, using in-plane ferromagnetic resonance (FMR) data on the acoustic mode of the coupled trilayer, we show that the coupling constant has an oscillatory dependence on the Mn thickness $t(\text{Mn})$.

The trilayer samples were prepared by molecular beam epitaxy on GaAs substrates. The $\text{Co}_{75}\text{Fe}_{25}$ (001) alloy layers are all about 100 Å thick and were grown using methods described earlier.³ They are bcc and exhibit reflection high energy electron diffraction (RHEED) patterns indicating excellent crystalline quality. The Mn interlayer thicknesses range from 6 to 30 Å as determined by x-ray fluorescence. They are single crystal as shown by RHEED, while extended x-ray-absorption fine structure (EXAFS) measurements show a tetragonally distorted bct structure.⁴ Vibrating sample magnetometer (VSM) and superconducting quantum interference device (SQUID) magnetometry, as well as 35 GHz FMR angular dependence, were carried out in plane near 300 K on all samples to measure their magnetic properties. All trilayers with $t(\text{Mn}) < 29$ Å exhibit evidence of coupling between the ferromagnetic (FM) layers.

The low-field VSM magnetization data for a strongly coupled sample are shown in Fig. 1. Note that the data seem to imply easy <100> and hard <110> behavior in the (001) plane, exactly the reverse of the behavior of isolated CoFe films with the above composition.³ However, if the Mn thickness is increased to 30 Å, the usual isolated film behavior is observed in both VSM and FMR. Thus, in this no-coupling limit, the two CoFe layers each have anisotropy parameters equal to those of an isolated film.

The above results can be understood easily if the magnetizations \mathbf{M}_1 and \mathbf{M}_2 of the CoFe layers of the coupled samples lie nearly perpendicular to one another in zero field, and along the expected in-plane <110> easy directions, so that the net magnetization $\mathbf{M} = \mathbf{M}_1 + \mathbf{M}_2$ is along <100> (see inset

in Fig. 1). For strong nearly 90° coupling, as found here, \mathbf{M}_1 and \mathbf{M}_2 initially rotate as a rigid unit in an attempt to align \mathbf{M} with \mathbf{H} when a field \mathbf{H} is applied along <110>, and they come together very slowly for \mathbf{H} applied parallel to \mathbf{M} along <100>. This type of behavior will be found as long as the coupling is large compared to both the in-plane anisotropy and $-\mathbf{M} \cdot \mathbf{H}$ energy density terms, as explicit calculations show. The SQUID magnetization data for $\mathbf{H} \parallel \langle 110 \rangle$ are shown for the same sample over a much more extended range in Fig. 2. Note that after the magnetization break near 1 kOe (when the above rotation is complete), M continues to increase and approaches saturation slowly above 20 kOe.

In order to determine the magnitude and form of the coupling, one must make a quantitative fit to the above data (and the corresponding $\mathbf{H} \parallel \langle 100 \rangle$ data) by writing down the free energy per unit area,

$$F = F_c + F_a - \mathbf{H} \cdot (\mathbf{M}_1 + \mathbf{M}_2)t(\text{CoFe}), \quad (1)$$

where F_c is the coupling energy/area, F_a is the correspond-

FIG. 1. Magnetic moment vs magnetic field data for a CoFe/Mn/CoFe trilayer sample with $t(\text{Mn}) = 11.2$ Å. The in-plane magnetic field is along the directions indicated. Inset: Moment directions in zero field.

FIG. 2. Field dependence of the magnetization of the sample of Fig. 1 over an extended field range with $\mathbf{H} \parallel (110)$. Inset: Details of the low field region. The data are indicated by the open circles and the fits shown by the dashed and solid curves are discussed in the text.

ing anisotropy term, and $t(\text{CoFe})$ is the thickness of a FeCo layer. Based on our previous FMR measurements on isolated CoFe films, we expect F_a to contain cubic and in-plane uniaxial anisotropies with K_1/M and $|K_u/M|$ about -0.25 and 0.05 kOe, respectively.³ Further details can be found in Ref. 1.

The usual coupling which has been found experimentally in the many types of magnetic trilayer and superlattice samples studied to date has the form

$$F_c = -2A_{12}\hat{\mathbf{M}}_1 \cdot \hat{\mathbf{M}}_2 - 2B_{12}(\hat{\mathbf{M}}_1 \cdot \hat{\mathbf{M}}_2)^2, \quad (2)$$

where A_{12} and B_{12} are the so-called bilinear and biquadratic coupling constants, respectively, and $\hat{\mathbf{M}}_i$ is a unit vector in the direction of \mathbf{M}_i . The values of A_{12} and B_{12} observed in other systems generally oscillate and decrease in magnitude as the interlayer thickness increases.⁵ If $|B_{12}| \gg |A_{12}|$ and $B_{12} < 0$, the configuration $\mathbf{M}_1 \perp \mathbf{M}_2$ is favored. Both Fe/Cr/Fe and Fe/Al/Fe trilayers have this 90° configuration for some interlayer thicknesses⁶⁻⁹ but this is not the usual behavior for coupled magnetic films.

Slonczewski² proposed a new form of coupling in which strong deviations from bilinear coupling are attributed to quasiantiferromagnetic exchange coupling within the interlayer itself. Due to competition between areas of differing interlayer thickness which favor either alignment or anti-alignment of the FM layers, the mean coupling has the following anticipated form:

$$F_c = C_+(\phi_1 - \phi_2)^2 + C_-(\phi_1 - \phi_2 - \pi)^2, \quad (3)$$

where C_+ and C_- are the FM and AFM coupling constants and ϕ_i is the in-plane orientation angle of \mathbf{M}_i . For $C_+ \approx C_-$, it is easy to show from Eq. (3) that the favored configuration² has \mathbf{M}_1 and \mathbf{M}_2 nearly 90° apart.

The dashed and solid lines in Fig. 2 are least-squares fits to the data based on free-energy expressions using the coupling forms of Eq. (2) (dashed) or Eq. (3) (solid). At each field, F is minimized, yielding the orientations of \mathbf{M}_1 and \mathbf{M}_2 as well as the moment along the field. Note that the Eq. (2)

FIG. 3. Dependence of the resonance field of the acoustic (in-phase) FMR mode on the in-plane field angle for two samples with $t(\text{Mn})$ equal to 8.7 and 29.1 Å.

best fit, for which $2A_{12} = 0$ and $2B_{12} = -3.0$ ergs/cm², is rather poor above the break in the curve and shows an abrupt rather than a slow approach to saturation. Previously, the largest value of $2B_{12}$ found is -0.3 ergs/cm² for Fe/Al/Fe.⁹

Conversely, Eq. (3) type coupling gives a much better fit over the entire range of fields with the following parameters: $C_+ = 0.95$ ergs/cm² and $C_- = 1.07$ ergs/cm², with $K_1/M = -0.34$ kOe and $K_u/M = 0.03$ kOe. Note that $C_+ \approx C_-$, as expected for the zero field 90° orientation found. The fit for the $\mathbf{H} \parallel (100)$ data using the same parameters (not shown) is similarly improved by using the Slonczewski coupling model of Eq. (3).

The above data thus offer strong evidence that Eq. (3) is the proper coupling for CoFe/Mn/CoFe and, furthermore, imply that the Mn interlayer is antiferromagnetically ordered, at least for small $t(\text{Mn})$. Recent soft x-ray magnetic circular dichroism and polarized neutron diffraction measurements on multilayers of CoFe/Mn, with $t(\text{Mn})$ chosen for very strong coupling, support the existence of Mn moments¹¹ as well as the near- 90° orientation of adjacent CoFe layer moments.¹⁰

We now consider the FMR behavior of the trilayer samples and show how it can be used to obtain the $t(\text{Mn})$ dependence of the coupling constant C_+ . In the following, only the in-phase or acoustic FMR mode of the coupled layers is considered and, based on the preceding discussion, the coupling is assumed to have the Eq. (3) form. The free-energy expression of Eq. (1) must be expanded by including the demagnetizing term $-2\pi(M_{1z}^2 + M_{2z}^2)t(\text{CoFe})$ and an extra coupling term $C_z(\theta_1 - \theta_2)^2$ to deal properly with the out-of-plane motion of the moments. Once this is done, one can use the coupled mode technique discussed earlier for Fe/Cr/Fe¹² to calculate the angular dependence of the acoustic FMR mode in terms of the coupling and anisotropy parameters.

The experimental angular dependences of the resonance field H_r are shown in Fig. 3 for two trilayers as the magnetic

FIG. 4. Calculated angular dependence of the acoustic mode FMR field for the $2C_+$ values indicated (in ergs/cm²). This calculation assumes $C_- = C_+ = 1.5C_z$ as found in Ref. 1.

field is rotated in the plane of the sample. As mentioned earlier, for $t(\text{Mn}) \geq 29 \text{ \AA}$ the FMR mode behaves essentially like that of an isolated CoFe film. For samples which show strong coupling, such as the 8.7 \AA Mn sample, the apparent fourfold anisotropy is greatly reduced in amplitude and it can even be reversed in sign for yet stronger coupling. Since all the CoFe films have about the same thickness, it seems very unlikely that the true anisotropy behaves in this way. Using the above mode calculation technique, the expected angular dependence was calculated for a number of fixed values of C_+ with all other parameters including K_1 fixed. The results are given in Fig. 4 and clearly show a reduced angular variation as the coupling is increased. The physical reason for this is that, for strong coupling, \mathbf{M}_1 and \mathbf{M}_2 are not aligned along the resonance field \mathbf{H} but are symmetrically displaced about it. As a result, the local curvatures of the free-energy surface seen by \mathbf{M}_1 and \mathbf{M}_2 as they precess are reduced in magnitude from the uncoupled case.

By comparing the observed variation in fourfold anisotropy with $t(\text{Mn})$ with that calculated for different coupling values C_+ in Fig. 4, one can deduce the dependence of C_+ on Mn thickness. The results of this comparison are shown in Fig. 5 and indicate that the coupling amplitude oscillates with an ill-defined period of about 7 or 8 \AA as $t(\text{Mn})$ increases. It will be interesting to see if future theoretical coupling models can reproduce this behavior.

FIG. 5. Deduced dependence of the coupling coefficient $2C_+$ on the Mn interlayer thickness $t(\text{Mn})$.

We believe that this system, which employs metastable bct Mn to couple the CoFe ferromagnetic layers, represents a new departure for studies of coupled layers, and the strong near-90° coupling at room temperature may prove useful for technological applications.

We describe the consequences on the interlayer exchange coupling by the addition of a small amount of Ag impurities within the Co layers of high crystalline quality Co/Cu/Co(Ag) and Cu/Ru/Co(Ag) trilayers, while maintaining the integrity of the spacer layers. We discuss the consequent changes in the amplitude, period, and phase of the coupling in terms of the modification of interfacial spin-dependent potentials. © 1996 American Institute of Physics.

[S0021-8979(96)48608-0]

Since the first observations of exchange coupling in magnetic multilayers,^{1,2} much effort has been expended in attempting to elucidate the microscopic details of the coupling mechanism. Various models with varying degrees of complementarity have been advanced to explain the interlayer interaction³⁻⁶ and its oscillation when the thickness of any of the films is changed. The exchange coupling can be thought of either as a form of RKKY interaction, a consequence of size quantization for electrons confined within the layers, or in terms of spin-dependent transmission and reflection across the ferromagnetic/nonmagnetic metal interface. In turn, these have suggested experimental refinements designed to discriminate between the predictions of the various competing theoretical treatments.

Along this idea, we have studied the effect on the interlayer exchange coupling with the variation of the spin-dependent potentials at the interfaces while causing *minimal* perturbation of the interlayer band structure. To this end, we have doped the *magnetic* layers with varying percentages of nonmagnetic impurities while leaving the constitution of the nonmagnetic spacer layer unaltered. This doping causes various changes which will be discussed in detail in this paper.

We chose to investigate two experimental trilayer systems. In each the magnetic metal chosen was Co and the impurity metal with which it was doped was Ag. The spacer materials were, respectively, Cu and Ru. This selection was prompted by the contrast in electronic "*d*" band structure between these two metals. In Cu, the *d* band is completely below the Fermi level, while in Ru the Fermi level lies within the *d* band and the *d* electrons may be expected to play a significant role in mediating the magnetic coupling.

The samples were prepared by molecular-beam epitaxy on a smooth and clean single crystalline hcp (0001) 100-Å-thick Ru buffer layer deposited on a mica substrate at a pressure less than 2×10^{-10} mbar. First the pure Co film is deposited, then the interlayer (Ru or Cu) followed by the Ag-doped Co. The film growth is monitored by reflection high energy electron diffraction (RHEED). As Co and Ag are im-

miscible metals, the substrate temperature is held at 240 K to discourage clustering of the Ag impurities within the impure Co layer and hence maximize charge transfer within the metastable alloy. Cross-sectional transmission electron microscopy indicates that phase separation has been very effectively suppressed since the size of the Ag aggregates present is less than the resolution of the instrument, which is 15 Å diameter or less.

Overall, the RHEED patterns obtained during the sample growth (Fig. 1) reveal well-defined structures which suggest good crystalline quality throughout the deposition. The quality of the Ru buffer layer in particular is evident from the

FIG. 1. Pairs of RHEED patterns observed during growth along two azimuths (11 $\bar{2}$ 0) and (10 $\bar{1}$ 0) for the Ru buffer layer and subsequent growth: (a), (b) after deposition of 100-Å-thick Ru buffer layer; (c), (d) after deposition of the pure 32-Å-thick Co layer; (e), (f) after deposition of 30-Å-thick Ru interlayer; (g), (h) for deposition of the impure Co₉₂Ag₈ layer with the same amount of Co as the previous Co layer (32 Å).

narrowness of the streaks and the presence of a 2×2 reconstruction [Figs. 1(a) and 1(b)]. The pure Co [Figs. 1(c) and 1(d)] grows epitaxially on the Ru buffer with the hexagonal basal plane parallel to the surface as may be seen from the patterns for the two azimuthal directions. Using three-dimensional (3D) RHEED diffraction analysis on the pure Co layers, it is observed that there is a high content of fcc (111) character in the growth [Figs. 1(c) and 1(d)].

For the Co/Cu/Co trilayers, the RHEED patterns observed along the (1120) and (1010) directions at the end of the Cu layer correspond to epitaxial pseudomorphic growth on top of the pure Co layer. As the Cu growth proceeds, the streaks become more intense and thinner with marked decrease of spot intensity. This indicates that the Cu tends to adopt a two-dimensional (2D) growth mode which is almost certainly favored by the small lattice mismatch between Co and Cu. Moreover, the RHEED information from the impure Co layer grown on top of the Cu retains the same features.

The RHEED patterns for the Ru spacer layer in the Co/Ru/Co systems are shown in Figs. 1(e) and 1(f). The deliberately enhanced 3D nature of the diffraction allows us to confirm that the structure is predominantly hcp. However, the most surprising feature of the RHEED data is seen in Figs. 1(g) and 1(h) where it is apparent that the *impure* Co grown on the Ru layer follows the hcp morphology of the latter. This is in contrast to the behavior of the pure Co growth, which, as discussed by Zhou *et al.*,⁷ possesses a high concentration of stacking faults and looks like a mixture of hcp and fcc.

As already discussed, the RHEED and x-ray data show that, at least for the Co/Ru/CoAg systems, the epitaxy of the Co is maintained in the presence of the Ag impurities, and that the overall structural quality has improved with reduced stacking fault density and better-defined growth morphology. This in turn suggests that the Co band structure may not be seriously modified, particularly at these relatively low impurity concentrations. Moreover, since the Ag clusters are very small, a high degree of charge transfer may be expected with consequent adjustment in the doped Co Fermi energy.

The ferromagnetic resonance (FMR) measurements of the Co/Ru/Co, Co/Ru/Co₉₇Ag₃, and Co/Ru/Co₉₂Ag₈ systems show two resonance modes, a strong acoustic mode and a weak optic mode for most of the samples when the external field was rotated from the parallel to the perpendicular direction to the film plane. In the symmetric Co/Ru/Co structure, the magnetization vectors of the two Co layers are antiparallel coupled when the Ru thickness t_{Ru} is in the range of $t_{\text{Ru}} < 13 \text{ \AA}$ and $18 \text{ \AA} < t_{\text{Ru}} < 25 \text{ \AA}$, but parallel coupled for the 16 \AA -Ru thick sample. While a similar coupling behavior is observed for the Co/Ru/Co₉₂Ag₈ structure except at low Ru thicknesses, the coupling behavior differs significantly in the Co/Ru/Co₉₇Ag₃, showing an antiparallel coupling for the 16 \AA -Ru thick sample and parallel coupling for $18 \text{ \AA} < t_{\text{Ru}} < 25 \text{ \AA}$. For the 12 \AA -thick Ru sample, the optic mode cannot be observed suggesting that the coupling is very small. In the analysis of the FMR data, only the effective anisotropy field, and the bilinear exchange field $H_{\text{ex}} = 2A_{12}/t_{\text{Co}}M_s$ ($A_{12} > 0$ for antiparallel coupling of the magnetic layers) are included.⁸ The analysis of the FMR data concerning the Co/Cu systems

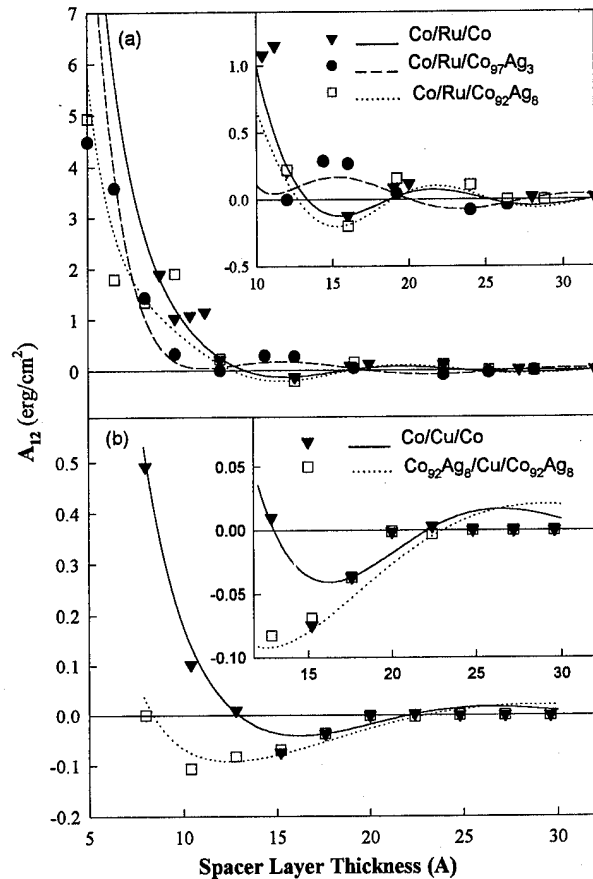

FIG. 2. Variation of the exchange coupling constant as a function of the spacer-layer thickness (a) for the three series of samples with Ru spacer layer (b) for the two series of samples with Cu spacer layer. The best fit for the data using Eq. (1) is shown.

has already been described by Zhou *et al.*⁹ The results are shown in Figs. 2(a) and 2(b). Concentrating initially on the data for the trilayers with pure Co films, two features are immediately apparent.

First, the difference in coupling strengths for the Cu and Ru spacer-layer systems is striking. The coupling in the Ru systems is about an order of magnitude stronger. This observation was anticipated in our initial choice of two complementary spacer-layer materials, it being expected that the broad partially filled *d* bands of the Ru would afford more significant interlayer interaction.

Second, in the coupling data of the Co/Ru/Co trilayers there is clearly a strong antiferromagnetic bias at low spacer-layer thicknesses. As shown in Fig. 2(a), the best fit for the exchange coupling is obtained using an additive exponential decay to the sinusoidal term of the following form with the fit parameters given in Table I:

$$A_{12} = a \times \exp(-t_{\text{Ru}}/d) + b \times \sin(q \times t_{\text{Ru}} + \phi)/t_{\text{Ru}}^2. \quad (1)$$

This is exactly what has been predicted by Shi *et al.*³ for Ru metal spacers. This prediction is based on an analysis of the effect of superexchange between the magnetic layers which concludes that the oppositely signed biases of RKKY and superexchange coupling mechanisms no longer cancel in

TABLE I. The fitting parameters for the exchange coupling obtained using Eq. (1) for both Ru and Cu spacer trilayers. The calculated curves are shown in Fig. 2.

Samples	a (erg/cm ²)	d (Å)	b (10 ⁻¹⁶ erg)	q (1/Å)	ϕ (π)
Co/Ru/Co	240	1.7	35.8	0.49	1.07
Co/Ru/CoAg ₃	240	1.6	39.8	0.42	0.32
Co/Ru/CoAg ₈	243	1.4	49.7	0.49	-0.95
Co/Cu/Co	28	1.8	12	0.31	-0.18
CoAg ₈ /Cu/CoAg ₈	20	1.2	18	0.21	0.46

the presence of a large density of states just above the Fermi surface. This prediction in turn is highly significant in interpreting the observed change in coupling as impurity is introduced into one of the magnetic layers.

Turning now to the exchange coupling for the impure magnetic layers, we consider first the Ru spacer systems Co/Ru/Co(Ag). For large thicknesses, the coupling may be fitted satisfactorily using the same procedure as for the symmetric trilayer systems and it is apparent that the change in spin-dependent potentials produces a shift in the phase while the period and amplitude are not significantly altered. For small spacer thicknesses, the AF bias is weaker than for the pure system, perhaps owing to a relative shift of the Fermi level and the singularity in Ru density of states.

The behavior of the impure Co/Cu/Co trilayers is rather

different. As seen in Fig. 2(b), 8% Ag impurity is enough to change the sign of the coupling for spacer thicknesses between 10 and 12 Å. In contrast with the previous case, the exchange coupling can be fitted very satisfactorily using either an additive [Fig. 2(b)] or a functional exponential decay to the sinusoidal term. Using both functions, these data could be interpreted as a significant increase in the period of the exchange coupling together with a reduction in amplitude. In turn this may be attributed to alteration of the interfacial scattering potentials perhaps owing partially to moderation of the “ s - d ” mixing.

We have studied the magnetic properties of Co/Cr/Fe multilayers by means of magneto-optic methods. These multilayers are of special interest because they combine different anisotropies and exchange coupling through the nonmagnetic Cr-spacer layer which was found to oscillate from ferromagnetic to antiferromagnetic coupling. The samples were grown by MBE methods on MgO(100) substrates at temperatures of about 300 °C. The fourfold crystalline symmetry is also obtained in the magnetic easy axis structure of Fe and Co. From the results of magneto-optic Kerr hysteresis loops we were able to distinguish between crystalline anisotropy and exchange coupling contributions. Additional monitoring of the domain structure by applying longitudinal Kerr microscopy was necessary to identify the regime where magnetization reversal occurs via domain wall motion or coherent rotation of the magnetization of the entire layer, respectively. From these results we were able to perform numerical simulations of the micromagnetic properties of trilayer samples. We discuss the results in terms of bilinear and biquadratic coupling. © 1996 American Institute of Physics. [S0021-8979(96)58708-8]

Magnetic coupling in Co/face-centered-cubic Fe/Co sandwiches

Ferromagnetic (FC) and antiferromagnetic coupling (AFC) of Co layers across a metastable fcc Fe spacer layer has been observed. Room-temperature-grown Fe on Co/Cu(100) was chosen as a spacer layer because it exhibits three distinct structural and magnetic phases depending on the thickness range: fct and ferromagnetic (region I), fcc and nonferromagnetic (region II), bcc and ferromagnetic (region III) (listed in order of increasing thickness). Co/Fe/Co sandwiches were grown on Cu(100) by molecular beam epitaxy with a base pressure of $\sim 2 \times 10^{-10}$ Torr, and characterized by low-energy electron diffraction and reflection high-energy electron diffraction. The magnetic properties were studied *in situ* using surface magneto-optic Kerr effect. Using a wedged Fe spacer layer, we investigated the magnetic coupling between Co films across many thicknesses of Fe. We found FC in region I, strong AFC at the boundary between regions I and II, and weak AFC in region II. We also studied the effect of just the Co overlayer on the metastable fcc Fe. We find that Co/Fe/Cu(100) differs qualitatively from Fe/Co/Cu(100). Finally, we find an oscillation in the AFC with a periodicity of ~ 12 Å by artificially increasing the thickness range of region II. © 1996 American Institute of Physics. [S0021-8979(96)48708-8]

It is well known that Fe has bcc structure at low temperatures and fcc structure at high temperatures ($T > 910$ °C). The lattice matching between fcc Fe and fcc Cu led to the idea of stabilizing the metastable phase of fcc Fe at room temperature either as particles in a Cu matrix or as thin films on top of a Cu substrate. Both ferromagnetic and antiferromagnetic states have been found in this metastable phase of fcc Fe, which depends sensitively on the preparation conditions. In particular, the room temperature growth Fe films on Cu(100) were shown to exhibit three distinct phases.^{1,2} For thickness less than 5 monolayers (ML), the films have a fct structure (a distorted fcc structure, see Ref. 3 for details) and are in the ferromagnetic state. Between 5 to 11 ML, the films have a fcc structure and are antiferromagnetic with a surface magnetic live layer. Above 11 ML, the films revert to the natural bcc state. These magnetic phases are believed to be correlated with the structural changes in the films. Recent structural analysis⁴ indicates that within the above three different phases, there are different crystal reconstructions at both the surface and the sublayers of the films. These complicated structural phases made it very difficult to analyze the structural effect on the magnetic phases of the films.

In an attempt to separate the structural and the electronic effects of the substrate on the magnetic properties of the fcc Fe overlayer, we investigated the Fe films grown on fcc Co(100) substrate. Since fcc Co can be stabilized on Cu(100) with exactly the same in-plane lattice spacing, we expect a similar structure for Fe films on Co(100) as on Cu(100). On the other hand, Co is ferromagnetic and Cu is not. Therefore, any different magnetic behavior in the Fe/Co(100) system as compared to the Fe/Cu(100) system should be caused by the Co-Fe magnetic interaction. Detailed results on the Fe/Co(100) system are reported in another paper⁵ of this proceedings. Basically, we got three distinct phases for different thicknesses of the Fe film. Different from the Fe/Cu(100) system which shows a perpendicular magnetization and a surface magnetic live layer between 5–11 ML, the Fe/

Co(100) system shows an in-plane magnetization and an interface magnetic live layer between 5–11 ML. Figure 1 summarizes our results: region I ($d_{\text{Fe}} < 5$ ML) is fct ferromagnetic, region II ($5 \text{ ML} < d_{\text{Fe}} < 11 \text{ ML}$) is fcc nonferromagnetic with an interfacial magnetic live layer, and region III ($d_{\text{Fe}} > 11 \text{ ML}$) is bcc ferromagnetic.

To further explore the magnetic nature of the fcc Fe films, we applied the fcc Fe as a spacer layer to investigate the magnetic coupling between two Co films. Antiferromagnetic coupling (AFC) between two ferromagnetic layers across a nonferromagnetic spacer layer was first found in an Fe/Cr/Fe sandwich.⁶ Many other systems were also found to exhibit a similar behavior. The materials for the spacer layer include antiferromagnets (e.g., Cr and Mn),^{7–9} nonmagnetic metals,¹⁰ and other nonmetallic elements (e.g., Si and silicides).^{11,12} The oscillations in the magnetic coupling are related to the spanning vector of the Fermi surface of the spacer layer. Since region II of the fcc Fe exhibits nonferro-

FIG. 1. M_{sat} from longitudinal surface magneto-optic Kerr effect vs Fe thickness for molecular beam epitaxy-grown Fe/Co(6 ML)/Cu(100) and Fe/Co(10 ML)/Cu(100), with the uniform Co signal subtracted out. Room-temperature growth and measurement shows three regions, all with in-plane magnetization: (I) fct and ferromagnetic, (II) fcc and nonferromagnetic with a magnetic live layer, (III) bcc and ferromagnetic. The reconstructions observed by low energy electron diffraction are also presented above. From Ref. 5.

FIG. 2. Longitudinal SMOKE hysteresis loops for Co(15 ML)/Fe/Co(15 ML). Many Fe thicknesses (d_{Fe}) were studied by using a wedged Fe layer. Four representative loops are shown: (a) $d_{\text{Fe}}=2.5$ Å. Ferromagnetic coupling was found for d_{Fe} in region I (see Fig. 1). (b) $d_{\text{Fe}}=8.2$ Å. Strong AFC was found at the boundary between regions I and II. We were not able to saturate the magnetization with our electromagnets ($H < 1.9$ kOe) (Note: H greater than 600 Oe caused our sample manipulator to move. We subtracted out the background signal due to this motion.) (c) $d_{\text{Fe}}=12.7$ Å. Weak AFC was observed for d_{Fe} in region II. (d) $d_{\text{Fe}}=15.2$ Å. The weak AFC is beginning to get "stretched out," signifying either the beginning of the fcc-bcc transition or a strong AFC oscillation. Loops (a) and (b) were easily reproducible, while (c) and (d) were not.

magnetic character, an investigation on the AFC across fcc Fe may help in understanding the magnetic phase of the fcc Fe in that thickness range.

A series of ultrathin film Co/Fe/Co and Co/Fe samples were grown by molecular beam epitaxy (MBE) on Cu(100) in an ultrahigh vacuum (UHV) chamber with a base pressure of $\sim 2 \times 10^{-10}$ Torr. The deposition rates were 0.5–4.8 Å/min for Co, and 0.6–1.7 Å/min for Fe. Structural characterizations were performed with reflection high energy electron diffraction (RHEED) and low energy electron diffraction (LEED). Magnetic properties were studied using an *in situ* surface magneto-optic Kerr effect (SMOKE) setup. Two pairs of electromagnets provided longitudinal [along the (011) direction] and polar magnetic fields up to 1.9 kOe.

The single crystal Cu(100) substrate was mechanically polished down to 0.25 μm diamond paste and finished with vibratory polishing using 0.05 μm Al_2O_3 powder. The substrate was cleaned *in situ* with cycles of Ar^+ sputtering at 2–5 keV and annealing at 650 °C.

"Symmetric" Co/Fe/Co sandwiches with Co thicknesses of 13, 15, 20, and 40 ML were fabricated at room temperature. The Co layers were of uniform thickness and the Fe layer was a wedge (0–30 Å).

Figure 2 shows a representative longitudinal SMOKE hysteresis loops observed in a Co(15 ML)/Fe/Co(15 ML) sample at room temperature. Figure 2(a) shows FC of the Co layers for Fe thicknesses (d_{Fe}) corresponding to region I of Fig. 1. Figure 2(b) shows strong AFC at the boundary between regions I and II. We call the AFC "strong" when we cannot saturate the magnetization with a 1.9 kOe magnetic

FIG. 3. M_{sat} from longitudinal SMOKE vs. Fe thickness for Co(15 ML)/Fe/Cu(100). Comparing with Fe/Co (Fig. 1) shows qualitative differences. For Fe/Co, M_{sat} increases linearly with the Fe thickness in region I. For corresponding Fe thicknesses in Co(15 ML)/Fe, M_{sat} is approximately constant.

field. Otherwise it will be called "weak." Figure 2(c) shows weak AFC for d_{Fe} in region II. It was found that the splitting of the loops changed very little as d_{Fe} varied from ~ 10 to ~ 15 Å. Figure 2(d) shows a "stretched out" AFC loop, for d_{Fe} in the thicker part of region II. This loop will be discussed later.

Loops 2(a) and 2(b) were easily reproducible, but loop 2(c) was not easily reproducible. Typically the loop was not well split. We hypothesized that structural instabilities of the fcc Fe might allow restructuring of the Fe as the Co overlayer is deposited. We based this on several observations.

First, we believed that a structural instability would not arise from the Co underlayer. The studies of fcc Fe/Co/Cu(100)⁵ performed in our lab showed that the structural and magnetic properties of Fig. 1 were easily reproducible. In fact, for each of our sandwiches we performed quick SMOKE measurements before putting on the Co overlayer. We found that for all samples the qualitative features of Fig. 1 persisted—linear increase in region I, and a drop to a roughly constant signal in region II. In addition, the LEED patterns of the Fe/Co/Cu(100) systems were sharp. During the growth of the Co overlayer, however, we were never able to obtain RHEED oscillations. This is in contrast to the Co underlayer growth where we were able to get ~ 30 oscillations with very little amplitude drop. Also, after growth the LEED patterns became diffuse.

To further support our idea, we investigated the properties of Co on fcc Fe without the Co underlayer. This allowed us to remove any effect that the Co underlayer may have had, thus isolating the effect of the Co overlayer. We first made an Fe wedge on Cu(100) and then grew a uniform Co layer on top of it. Figure 3 shows the result of a longitudinal SMOKE measurement for 15 ML Co. The middle region is flat, like region II of Fe/Co/Cu(100) (Fig. 1). The thicker region has increasing signal, like the fcc-bcc transition in Fig. 1. However, the thinner region does not have a linearly increasing signal like region I of Fig. 1. This result is consistent with the idea that the Co overlayer somehow changes the structural properties of the underlying fcc Fe. However, more studies are needed to determine the effect of overlayers on fcc Fe.

Returning to the Co(15 ML)/Fe/Co(15 ML) sample. Fig. 4 shows the magnetization (Kerr signal) at $H=200$ Oe vs. Fe thickness, taken from SMOKE hysteresis loops. This pro-

FIG. 4. Longitudinal SMOKE measurement of $M(H=200 \text{ Oe})$ vs. Fe thickness for the Co(15 ML)/Fe/Co(15 ML) sample. 200 Oe is sufficient to saturate the magnetization for the weak AFC and the ferromagnetic coupling across fcc Fe. However, it does not saturate the magnetization for the strong AFC or in the fcc-bcc transition region. Hence dips in $M(H=200 \text{ Oe})$ signify the onset of the strong AFC or the fcc-bcc transition. The first dip at $\sim 7 \text{ Å}$ is strong AFC. The second dip at $\sim 17 \text{ Å}$ is due to either strong AFC or the onset of the fcc-bcc transition.

vides an efficient way of representing our data: 200 Oe is sufficient to saturate the magnetization for the weak AFC in region II but not enough to saturate the magnetization for a strong AFC. Hence dips in $M(H=200 \text{ Oe})$ signify a strong AFC peak. The first dip at $d_{\text{Fe}} \sim 7 \text{ Å}$ is a strong AFC peak. The second dip is ambiguous because of the onset of the fcc-bcc transition.

Thus loop 2(d), which lies at the beginning of the second dip, poses an interesting question. Does the stretching out of the loop signify the beginning of the fcc-bcc transition, or does it signify the development of a strong AFC peak? Perhaps there would be another strong AFC peak if the fcc-bcc structural transition did not occur. Unfortunately, the fcc-bcc transition begins and the structure of the Fe changes drastically before a strong AFC peak can fully develop.

To examine this issue, we made a compromise. We know from Li *et al.*¹³ and our own experience, that if the Cu(100) substrate is "dirty" (has a few percent of carbon and oxygen impurities), the fcc phase of Fe can persist to a higher thickness. Of course the fcc Fe on a dirty substrate will be different from the fcc Fe on a clean substrate, but we assume the difference is negligible with regard to the *existence* of a second strong AFC peak. We made a Co(6 ML)/Fe/Co(6 ML) sample on a dirty substrate which contains of a few percent of carbon and oxygen impurities. The signature of a dirty film in practice is that region II in Fig. 1 gets bigger and that the surface reconstruction is 2×2 instead of 2×1 .¹⁴ Figure 5 shows the Kerr signal before and after the Co overlayer was grown. The Fe/Co signal shows that the fcc region is indeed longer. To study the oscillations of the magnetic coupling in the Co/Fe/Co sandwich, we measured the magnetization (Kerr signal) at a field of 200 Oe, as before. Two dips were observed, each signifying a strong AFC peak. We conclude that we have found an oscillation in the AFC with a periodicity of $\sim 12 \text{ Å}$. It is interesting to note that the first AFC

FIG. 5. Longitudinal SMOKE measurements of $M(H=200 \text{ Oe})$ vs. Fe thickness for Fe/Co(6 ML) and Co(6 ML)/Fe/Co(6 ML), on a dirty Cu(100) substrate. The dirty substrate allows the fcc structure to persist to a higher Fe thickness, allowing a second strong AFC peak to fully develop. The Fe/Co measurement verifies that region II is longer than usual; it normally ends at $d_{\text{Fe}} \sim 20 \text{ Å}$. The Co/Fe/Co measurement shows a second dip at $d_{\text{Fe}} \sim 19 \text{ Å}$ signifying a strong AFC peak.

occurs at the transition point between regions I and II. We do not know if this is a coincidence or if this is somewhat associated with the fct-fcc structural transition.

We have observed FC, strong AFC, and weak AFC in the Co/fcc Fe/Co sandwiches grown on Cu(100). We have shown that Co/Fe/Cu(100) is different from Fe/Co/Cu(100). This could be due to an instability in the structure of epitaxial fcc Fe. How this instability affects the coupling is not yet understood and requires further investigation. We have also observed an oscillation in the coupling. A strong AFC peak exists at d_{Fe} corresponding to the boundary between regions I and II of Fe/Co/Cu(100). By using a dirty sample to artificially lengthen the flat region, we also find strong AFC at $d_{\text{Fe}} \sim 19 \text{ Å}$.

Transport and magnetism correlations in thin-film ferromagnetic oxides

M. F. Hundley, J. J. Neumeier, R. H. Heffner, Q. X. Jia, X. D. Wu, and J. D. Thompson

Materials Science and Technology Division, Los Alamos National Laboratory, Los Alamos, New Mexico 87545

To determine the T_c dependence of the colossal magnetoresistance (CMR) exhibited by the ferromagnetic $\text{La}_{0.7}\text{A}_{0.3}\text{MnO}_{3+\delta}$ ($\text{A}=\text{Ba}, \text{Ca}, \text{Sr}$) system, we examine the magnetic-field and temperature-dependent resistivity and magnetization of a series of thin films that were grown via pulsed-laser deposition. The films had magnetic ordering temperatures (T_c) ranging from 150 to 350 K. All samples display a large negative MR that is largest near T_c , and samples with a low T_c display significantly larger MR values than do samples with large T_c 's. The quantity $\rho(T_c)/\rho(4 \text{ K})$, the amount by which the resistivity is reduced by full ferromagnetic order, varies as $\exp(E_a/T_c)$ with an activation energy $E_a=0.1 \text{ eV}$. These results indicate that the magnitude of the CMR effect in a given specimen is controlled not by $\rho(T_c)$, but by T_c via the ratio $\rho(T_c)/\rho(4 \text{ K})$. Phenomenological scaling relationships are also reported that link $\rho(H, T)$ to both H and $M(H, T)$. © 1996 American Institute of Physics. [S0021-8979(96)48808-4]

The recent observations¹⁻³ of a colossal negative magnetoresistance (MR) near T_c in the ferromagnetic (FM) doped lanthanum manganites ($\text{La}_{1-x}\text{A}_x\text{MnO}_{3+\delta}$, $\text{A}=\text{Ba}, \text{Ca}, \text{Sr}$) has sparked renewed interest in this system. The divalent substitution for La^{3+} leads to a mixed $\text{Mn}^{3+/4+}$ valence, a ferromagnetic ground state driven by double-exchange,⁴ a metal-insulator transition at $T_{\text{MI}}=T_c$, and the colossal magnetoresistance (CMR) effect. The unusual temperature- and magnetic (H)-field-dependent resistivity exhibited by these compounds reflects a novel interplay between magnetism and electronic transport that does not occur in conventional metals, ferromagnets, or semiconductors. Recent publications have focused on the magnitude of the MR effect,³ the interplay between magnetic order and electronic transport,⁵⁻⁷ and the effects of oxygen stoichiometry⁸ on the transport and magnetic properties.

To determine the dependence of the CMR effect on T_c , we examine the temperature- and H -field dependent resistivity $\rho(H, T)$ of a series of $\text{La}_{0.7}\text{A}_{0.3}\text{MnO}_{3+\delta}$ thin-films ($\text{A}=\text{Ba}, \text{Ca}$, and Sr) with T_c 's ranging from 150 to 350 K. Both the zero-field resistivity and the magnetoresistance are strongly dependent upon a given film's ordering temperature; low- T_c films exhibit a substantial negative MR, while films with T_c 's above 300 K exhibit a more modest MR ratio. We also find that a direct correlation exists between $\rho(H, T)$ and $M(H, T)$ near and below T_c . In addition, the MR at T_c follows a simple phenomenological expression that contains a single scaling parameter which is a monotonic function of T_c . The form of this scaling expression as well as the expression that links $\rho(H, T)$ and $M(H, T)$ provide important clues as to the nature of the underlying mechanisms responsible for the CMR effect.

Transport and magnetism measurements were performed on a series of six $\text{La}_{0.7}\text{A}_{0.3}\text{MnO}_{3+\delta}$ thin films grown via pulsed-laser deposition (PLD). The highly oriented, 1000-Å-thick films were deposited on (100) LaAlO_3 substrates in a

200 mTorr oxygen atmosphere. The films were post-annealed in flowing oxygen at 950 °C for ten hours. Sample T_c was controlled both by varying the dopant element A ,⁹ and by varying the substrate temperature T_s used during the deposition process. Growth parameters for each film, along with their respective magnetic ordering temperatures (determined from magnetization Arrott plots), are presented in Table I. The Ca-doped films (films 1-4) have T_c 's ranging from 150 to 290 K, while the Ba- and Sr-doped films (films 5 and 6) have T_c 's that are above room temperature. Both the FM transition width and the low-temperature saturation magnetization are T_s -independent. Details of the underlying sample-to-sample differences (stoichiometry, microstructure, etc.) that are responsible for the variation in T_c in the Ca-doped samples will be considered in a future publication;¹⁰ the variation is most likely due to an oxygen deficiency ($\delta<0$) that rises with increasing T_s .⁸ Four-probe ρ measurements were made with dc currents ranging from 1 nA to 10 μA . The magnetoresistance is defined here as $\Delta\rho/\rho_0=[\rho(H)-\rho_0]/\rho_0$, with $\rho_0=\rho(H=0)$. Magnetization (M) measurements were performed with a Quantum Design SQUID magnetometer.

The $H=0$ resistivities of the films with $T_c<300 \text{ K}$ are depicted in Fig. 1(a). Sample 1 ($T_c=152 \text{ K}$) exhibits a sharp

TABLE I. Stoichiometry, substrate temperature T_s , and magnetic ordering temperature T_c for the six $\text{La}_{1-x}\text{A}_x\text{MnO}_{3+\delta}$ thin-film specimens examined in this work. All films were post-annealed.

Sample number	A	x	T_s (°C)	T_c (K)
1	Ca	0.3	900	152
2	Ca	0.3	750	224
3	Ca	0.3	600	255
4	Ca	0.3	500	292
5	Ba	0.3	600	325
6	Sr	0.3	600	350

FIG. 1. (a) Resistivity vs temperature, and (b) 50 kOe magnetoresistance vs. temperature. The arrows indicate T_c for each sample while the integers indicate the sample number that corresponds to each data set.

drop in ρ below T_c [$\rho(4\text{ K})/\rho(T_c) = 5 \times 10^{-4}$] and activated behavior (activation energy $E_a \approx 0.1\text{ eV}$) above T_c . Samples 2 and 3 also exhibit activated behavior above T_c with similar E_a values. For the other samples, $\rho(T_c)$ progressively decreases with increasing T_c . Well below T_c , ρ saturates to a value near $100\text{ }\mu\Omega\text{ cm}$ for all samples. When normalized by their respective low- T resistivities, $\rho(T > T_c)$ roughly fall on a common curve for all samples.

The T -dependent magnetoresistance $MR(T)$ in 50 kOe is shown in Fig. 1(b). Sample 1 displays a wide, flat-topped peak centered at T_c with a maximum MR of $\Delta\rho/\rho_0 = -0.996$. With increasing T_c the MR data indicate the following trends: (a) the width of the MR peak decreases, (b) the MR peak temperature T_{max} shifts somewhat below T_c , (c) the magnitude of the MR peak decreases, and (d) $\Delta\rho/\rho_0$ is very small at $T \ll T_c$ for all six films. $MR(T)$ data measured in $H < 50\text{ kOe}$ indicate that T_{max} approaches T_c as H is increased. The H -dependent magnetoresistance $MR(H)$ for samples 1–6 at their respective ordering temperatures are shown in Fig. 2(a) in fields to 100 kOe. Sample 1's MR saturates at a value near $\Delta\rho/\rho_0 = -1$ in 25 kOe; sample 2's MR also saturates, but in a larger H field and at a smaller value of $\Delta\rho/\rho_0$. The magnetoresistance of samples 3–6 does not saturate even in the largest fields applied. Extrapolations of the MR data to $H > 100\text{ kOe}$ for these higher- T_c films suggest that the saturation values of $\Delta\rho/\rho_0$ decreases with increasing T_c .

The key finding from the $MR(T, H)$ data presented in Figs. 1 and 2 is that the size of the CMR effect decreases with increasing film T_c . This result is summarized in Fig. 2(b) where $\Delta\rho/\rho_0(50\text{ kOe})$ at T_c is plotted against sample T_c for films 1–6. The 50 kOe field essentially saturates the MR

FIG. 2. (a) Magnetoresistance vs. applied magnetic field measured at T_c for six samples (T_c for each curve is indicated on the right). (b) 50 kOe magnetoresistance measured at T_c for samples 1–6 plotted against sample T_c ; the solid line is a fit to the data (see text).

of sample 1 ($T_c = 152\text{ K}$), reduces ρ by 50% for the film with a T_c near room temperature, and only reduces ρ by roughly 20% for the high- T_c Sr-doped film (film 6). This CMR T_c dependence is simply a reflection of the fact that the order-induced drop in ρ that occurs below T_c is far larger in low- T_c samples than in high- T_c samples. This is made clear in Fig. 3, where $\rho(T_c)$ in both zero field and 50 kOe is plotted versus $1000/T_c$ for the six films; the resistivity is normalized by the low-temperature (4 K) saturation resistivity. The quantity $\rho(T_c)/\rho(4\text{ K})$ is a measure of the reduction in ρ brought on by complete FM order. In zero field $\rho(T_c)/\rho(4\text{ K})$ varies as

FIG. 3. Normalized resistivity plotted against $1000/T_c$ for samples 1–6 at their respective ordering temperatures in both zero field and 50 kOe.

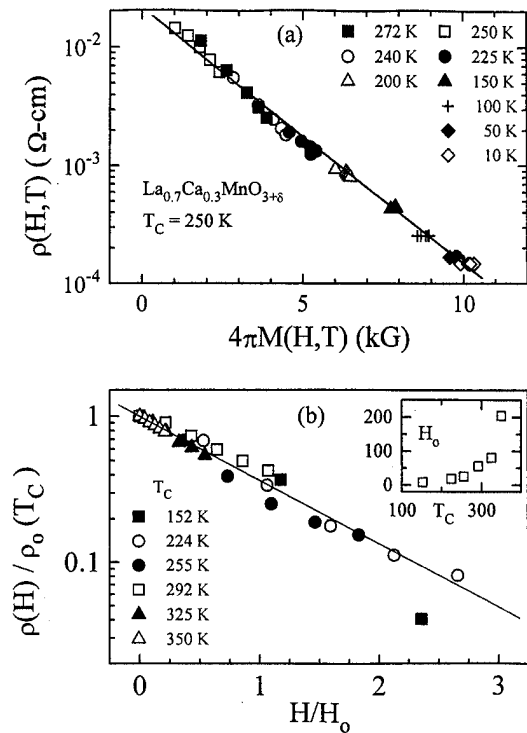

FIG. 4. (a) $\rho(H, T)$ vs. $M(H, T)$ for sample 3. At each T , points are included at $H=10, 20, 30, 40$, and 50 kOe. The solid line is a least-squares fit to the data. (b) Normalized magnetoresistance at T_c plotted vs. H/H_0 for samples 1–6; the scaling parameter H_0 (in kOe) is plotted against sample T_c in the inset.

$\exp(E_a/T_c)$ with an activation energy $E_a=0.1$ eV. This is the same activation energy evident in $\rho(T>T_c)$ in films 1–3. The normalized resistivity in 50 kOe is essentially T_c independent. The zero-field and 50 kOe results in Fig. 3 lead directly to the fit $\Delta\rho/\rho_0(T_c)=\alpha\exp(-E_a/T_c)-1$ that is displayed in Fig. 2(b) ($\alpha=20$). The data in Figs. 2(b) and 3 indicate that the key quantity that controls the MR in a given film is the normalized resistivity $\rho(T_c)/\rho(4\text{ K})$ (which is set by T_c), and not just $\rho(T_c)$. Hence, attempts to increase $\rho(T_c)$ by growth nonoptimization should also increase $\rho(4\text{ K})$, and would presumably have little effect on the magnitude of the CMR effect.

To determine how the enhancement in M and the huge drop in resistivity that occur below T_c are linked, measurements of $\rho(H, T)$ and $M(H, T)$ were made on sample 3 ($T_c=255\text{ K}$). The results are presented in Fig. 4(a), where $\rho(H, T)$ is plotted against $M(H, T)$ rather than as a function of H or T . The data were measured at nine temperatures from 272 to 10 K in fields from 10 to 50 kOe (where M reflects the local magnetization).⁵ The data exhibit a correlation encompassing a two order-of-magnitude variation in ρ that can be parametrized as $\rho(H, T)\propto\exp[-M(H, T)/M_0]$, with $4\pi M_0=2.0\text{ kG}$. The data follow this phenomenological expression both close to and below T_c ; the expression does not describe the data above 280 K where FM fluctuations are no longer present. The data in Fig. 4(a) clearly indicate that the magnetization and resistivity are inextricably linked in

the FM state. A similar relationship exists for the $MR(H)$ data plotted in Fig. 2(a). The field-dependent data at T_c for all six films can be scaled via the expression $\rho(H)/\rho_0(T_c)\propto\exp(-H/H_0)$, where the scaling parameter H_0 is T_c dependent. The scaled data appear in Fig. 4(b), with $H_0(T_c)$ plotted in the inset. With the exception of sample 1 in fields sufficient to saturate that film's magnetoresistance, the data are qualitatively well-described by this phenomenological expression. The scaling parameter H_0 is a simple, monotonically increasing function of T_c . The relationship that links ρ and H follows directly from that between ρ and M because the magnetization varies quasilinearly in H for fields much less than the saturation field at T_c .

The phenomenological relationships between ρ , M , and H may provide insight into the form of the transport mechanism in the CMR films. In the double exchange (DE) model, which is thought to explain the magnetism in the CRM compounds,⁴ the bandwidth W is proportional to the magnetization. Polaron hopping transport leads to a resistivity of the form $\rho\propto\exp(-W)$.¹¹ With $W\propto M$, polaron hopping and double exchange combine to give $\rho\propto\exp(-M)$, precisely that which is observed in Fig. 4(a). A somewhat surprising feature of the data is the fact that this exponential relationship persists down to temperatures well below T_c where it is reasonable to expect, given the drastic drop in ρ , that the polarons will be delocalized and transport would proceed via a conventional metallic process. The data in Fig. 4(a) may indicate that the quasiparticles evolve into large polarons at temperatures well below T_c . Additional theoretical and experimental work is needed to clarify this point.

In conclusion, field-dependent resistivity measurements on a series of six PLD-grown CMR films indicate that the magnitude of the CMR effect is determined by a given film's magnetic ordering temperature. Films with a low T_c exhibit both a large drop in the resistivity in the FM state and a large, negative magnetoresistance, while both effects are significantly smaller in films with a high ordering temperature.

This research was performed under the auspices of the U.S. Department of Energy.

We have explored the colossal magnetoresistance (CMR) effect in the antiferromagnetic $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ compound. In the absence of a magnetic field (H), the solid is a canted antiferromagnetic (AFM) insulator. An applied H in the Tesla scale induces a first order AFM to FM phase transition, and correspondingly, an insulator to metal transition. The observed CMR is attributed to the H -induced charge localization-delocalization behavior associated with the AFM-FM transition. At low temperatures ($T < 100$ K), the solid remains in the AFM phase, where we have observed a phenomenal one millionfold change in resistivity between 0 and 8 Tesla. The origin of CMR in low T -region is a thermal activation energy gap which is strongly dependent on H .

The magnetotransport and magnetic properties of the perovskite $\text{La}_{1-x}\text{A}_x\text{MnO}_{3+\delta}$ ($0 \leq x \leq 1$) system have received a great amount of attention recently after the discovery of the so-called colossal magnetoresistance (CMR) effect in the ferromagnetic phase (FM) of this system.¹⁻⁶ Essential to the CMR is the existence of the mixed valence state of Mn, evolving from Mn^{3+} (spin $S=2$) in the parent phase ($x=0$) to Mn^{4+} (spin $S=3/2$) in the end compound such as CaMnO_3 (i.e., $A=\text{Ca}$). The low energy t_{2g}^3 triplet contributes a local spin of $S=3/2$ to both Mn^{3+} and Mn^{4+} . In addition, Mn^{3+} has an additional electron in the e_g^1 state with its spin parallel to the local spin, whereas the e_g^1 state is empty in Mn^{4+} . Whether the e_g^1 electron is localized or mobile depends on the local spin orientation. If the local spins are aligned as in a FM, the e_g^1 electron will be mobile so as to lower its kinetic energy. However in the AFM configuration, the intra-atomic exchange between the e_g^1 electron and the local spin would forbid the electron transfer, hence, resulting in a charge localization. Because of these reasons, the electron transport in $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ is sensitive to an underlying magnetic structure and its dynamics.⁷ It is believed that the origin of CMR is directly related to this sensitivity.

To date, research on CMR has focused on the FM phase, in particular, on $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and other similar compounds.¹⁻⁴ CMR as large as ten-thousandfold has been obtained in polycrystals,³ single crystals,⁸ and epitaxial thin films.^{1,2} A maximum MR is generally associated with the FM phase transition. We have studied the CMR effect using a different approach, and have searched for the maximum MR with an emphasis on the AFM phase. As a consequence we have achieved record CMR values of 830 000% at $T=125$ K and $10^8\%$ at $T=57$ K in a well-prepared $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ compound. Coupled with such a dramatic CMR is a field induced AFM-FM first order phase transition. At low T , we have also observed a strongly field dependent activation energy gap in the AFM phase.

The bulk $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ compound was prepared using

a solid-state reaction method. Appropriate proportions of La_2O_3 , CaCO_3 , and MnO_2 precursors were thoroughly mixed and then pressed into pellets. The sintering process lasted over a long period of 150 h in an oxygen atmosphere. Two intermediate grindings and mixings were carried out for homogenization. The annealing temperature was 1200 °C for the first two sinterings and was 1300 °C for the last. The sample was cooled to room temperature in more than 8 h. Four-probe magnetoresistance was measured in a cryostat equipped with an 8 T magnet. The magnetization of the sample was measured using the Quantum Design SQUID magnetometer. X-ray diffraction analysis indicated that the sample has a single phase with a cubic perovskite structure. The lattice constant is 7.66 Å.

Figure 1 shows the temperature (T) dependence of resis-

FIG. 1. The temperature (T) dependence of the resistivity, $\rho(T)$, (in log scale) measured in zero and 8 T field for $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$. The magnetoresistance ratio defined as $[\rho_0(T) - \rho_{8T}(T)] / \rho_{8T}(T)$ is also shown. The arrows indicate directions of measurement.

FIG. 2. The T -dependence of magnetization $M(T)$ and inverse susceptibility $\chi^{-1}(T)$ measured at $H=150$ G and 5.5 T. By extrapolating $M(H)$ in the high- H region to $H=0$, we have obtained a small ferromagnetic spontaneous magnetization $M_s(T)$ which is shown in the lower panel.

tivity, $\rho(T)$, (in log scale) measured in 0 and 8 T field. The zero field $\rho_0(T)$ reveals a thermal hysteresis between 110 and 190 K in the cooling and warming-up mode. The $\rho_{8T}(T)$ at 8 T was measured only during warming-up. Over the T -range studied, $\rho_0(T)$ experiences a change spanning over eight orders of magnitude. Its T -dependence is semiconductorlike with an activation energy $\Delta(0) \approx 67$ meV. On the other hand, $\rho_{8T}(T)$ is substantially smaller than $\rho_0(T)$ at any given T . Above 120 K, $\rho_{8T}(T)$ is weakly dependent on T , having a value (a few m Ω -cm) typical of a poor metal. Below 120 K, $\rho_{8T}(T)$ experiences a sudden increase and evolves into an activation region with a gap $\Delta(8T) \approx 7.5$ meV, which is about one order of magnitude smaller than $\Delta(0)$. Also shown in Fig. 1 is MR ratio defined as $[\rho_0(T) - \rho_{8T}(T)]/\rho_{8T}(T)$. At $T \approx 60$ K ρ changes over six orders of magnitude between 0 and 8 T, and at $T \approx 125$ K over four orders of magnitude. To our knowledge the CMR effect shown here is the largest reported in $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ and similar systems. It is noted that the maximum CMR in the FM $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ occurs near T_c and vanishes as T approaches zero. However, in $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$, CMR seems to increase exponentially with reducing T .

To understand the anomalous magnetotransport, we have measured the magnetic properties of $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$. Figure 2 shows the T -dependence of magnetization $M(T)$ and inverse susceptibility $\chi^{-1}(T)$ measured in a low field (150 G)

FIG. 3. Magnetization curves $M(H)$ measured at various temperatures. Three magnetic states are shown schematically in various temperature regions: a canted antiferromagnet, a canted ferromagnet, and a paramagnet.

and a high field (5.5 T). We have also measured a series of $M(H)$ curves from 0 to 5.5 T and in the T -range between 5 and 230 K. Some representative $M(H)$ curves are shown in Fig. 3. By extrapolating $M(H)$ in the high- H region to $H=0$, we have obtained a small FM spontaneous magnetization $M_s(T)$, which is shown in the lower panel of Fig. 2. Based on Figs. 2 and 3, we describe some of the important features of the magnetic properties.

(1) There exist two magnetic transitions in the T -range studied. The high- T $\chi^{-1}(T)$ provides an extrapolated Curie-Weiss $T_c \approx 225$ K as shown in Fig. 2, indicating a FM transition from a paramagnetic state. Another magnetic transition occurs at a T_d lower than T_c . The transition temperature, T_d , depends on H and on thermal history (zero-field-cooled or field-cooled). The substantial drop of M below T_d is indicative of an FM-AFM transition. The thermal hysteresis in M vs T (see the middle panel of Fig. 2) reveals a first order phase transition.

(2) At a fixed T , the FM-AFM transition can also be induced by an applied H_d (see Fig. 3). At a low T (< 100 K), the solid is an AFM up to the maximum 5.5 T of our instrument. At a high T , for example, 150 K, the AFM-FM transition starts at about 4 T. As T approaches T_c , the AFM-FM transition shifts to a lower H , and becomes much smeared. In the zero H field, the solid is probably never a FM even at T near T_c . For example, at $T=205$ K, the $M(H)$ curve is hardly of any FM nature.

(3) Under a high H (e.g., 5.5 T), M approaches ~ 90 emu/g as $T \rightarrow 0$ K. Comparing with the theoretical limit of $M_0 = 102$ emu/g, one concludes that the canting angle θ_{FM} is about 56° at $H=5.5$ T in the FM phase [note that $\cos(\theta/2) = M_s^{\text{exp}}/M_0$.] On the other hand, in the AFM phase, the spin orientations are canted too as evidenced from a small FM $M_s(T)$ component shown in the lower panel of Fig. 2. We

estimated that $\theta_{\text{AFM}} \approx 165^\circ$. In other words, the AFM–FM transition, that can be either induced by H or by varying T , corresponds to a transition in θ from 165° to 56° .

With the above magnetic properties in mind, we can proceed to explain the magnetotransport data presented in Fig. 1. In zero field, θ remains large between 5 K and T_c . As a consequence, a charge transfer between neighboring sites is difficult, according to the prediction of the double exchange model^{9–11} that charge transfer integral t is proportional to $\cos(\theta/2)$. At low T , charges are almost fully localized, which leads a thermally activated $\rho_0(T)$. Neutron diffraction studies¹² on $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ have shown that Mn^{3+} and Mn^{2+} sites are spatially ordered at a low T similar to a Wigner lattice.

At a high H (e.g., 8 T), the system is FM above $T \approx 125$ K. In the FM phase, because of a much smaller canting angle, the charge transfer is enhanced substantially, allowing the formation of extended electronic states. The solid then behaves like a metal, albeit a poor one, with a resistivity of a few $\text{m}\Omega\text{-cm}$. At about 125 K, a FM–AFM transition occurs, causing a charge localization and a thermally activated transport. However, as mentioned earlier, the energy gap at 8 T is much smaller than that at zero field. This is due to the fact that the canting angle in the AFM phase is reduced in the high H region because of the Zeeman energy. A smaller canting angle makes the charge transfer easier. In short, the dramatic CMR effect in the low- T region observed in Fig. 1 is caused by the strongly H dependent energy gap $\Delta(H)$ in the AFM phase. This differs from the CMR mechanism in the FM $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$, where the effect of H is to suppress the randomness in spin orientation. The dynamics of the two phenomena, though related, is very different.

Recently Tomioka *et al.*,⁵ have studied a single crystal of $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$ which shows similar magnetic and transport properties to those presented here. The CMR effect they reported, however, is much smaller. Application of a field of 7 T changes ρ by about two orders of magnitude at $T \approx 0$ K.

Comparing with the $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ system that has a MR of one-millionfold, the latter seems to develop a much more rigid charge-ordered lattice, yielding a larger energy gap in the AFM phase. The metallic phases of the two systems, on the other hand, do share a similar resistivity (a few $\text{m}\Omega\text{-cm}$).

In summary, we have obtained record values of CMR in the AFM phase of $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$. At $T = 125$ K, the CMR is about one million percent. It increases exponentially to 100 million percent at 57 K. The CMR effect at intermediate T 's (e.g., 125 K) is associated with a field induced first order FM–AFM phase transition. In the low- T region (< 100 K), the AFM phase leads to a charge localization and, possibly, spatially charge ordering. The energy gap in the insulating AFM phase is dependent on H , with a higher H corresponding to a smaller gap. It is this particular nature of the energy gap in the AFM phase that brings about the phenomenal CMR effect.

Lattice effects on the magnetoresistance in doped manganese perovskites (abstract)

H. Y. Hwang,^{a)} S-W. Cheong, P. G. Radaelli,^{b)} M. Marezio,^{c)} T. T. M. Palstra, and B. Batlogg

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

A detailed study of doped LaMnO_3 with fixed carrier concentration has revealed a direct relationship between the Curie temperature T_c and the average ionic radius of the La site $\langle r_A \rangle$, which is varied by substituting rare earths of different ionic radii for La. With decreasing $\langle r_A \rangle$ magnetic order and significant magnetoresistance occur at lower temperatures with increasing temperature hysteresis, and the magnitude of the magnetoresistance increases dramatically. The predominant structural effect of decreasing $\langle r_A \rangle$ is to decrease the Mn–O–Mn bond angle, which is accompanied by slight variations in the Mn–O bond distance. These results demonstrate that the notion of “double exchange” must be generalized to include changes in the Mn–Mn electronic hopping element as a result of microstructural changes induced by composition, temperature and pressure variations. © 1996 American Institute of Physics. Electrical conductivity in ferromagnetic perovskite structures

Shufeng Zhang

Department of Physics, New York University, New York, New York 10003

A spin-polaron Hamiltonian is proposed to study the electrical conductivity in perovskite structures. A crossover from the metallic conduction at low temperatures to the hopping-type conduction at high temperature is calculated within the proposed model Hamiltonian. It is found that most of the experimental observations on resistivity and colossal magnetoresistance can be well explained with the assumption of the existence of spin clusters. © 1996 American Institute of Physics. [S0021-8979(96)48908-0]

The subject of magnetotransport properties of perovskite lanthanum manganite, i.e., $\text{La}_{1-x}\text{A}_x\text{MnO}_3$ ($\text{A}=\text{Ca}, \text{Ba}, \text{Sr}$, etc.), has received much attention recently¹⁻⁴ in spite of the fact that these materials have been known for quite a long time.^{5,6} There are two primary reasons for justifying the necessity for revisiting this "old" topic. First, new observations of the giant magnetoresistive effect at room temperature may lead to potential applications. Second, anomalous magnetic and transport properties in these materials have never been satisfactorily explained, in particular, no quantitative theory exists for understanding magnetotransport properties in these structures.

Since there are many competing interactions in perovskites, e.g., double exchange^{7,8} which favors ferromagnetic coupling and superexchange which favors antiferromagnetic coupling, the problem of magnetic structures becomes extremely difficult. One would expect quite complex and rich magnetic phases. Several possible magnetic phases have been suggested: canted moments,⁹ spiral structures,¹⁰ ferromagnetism,¹¹ disordered magnetization,⁹ magnetic clusters or giant spins,¹² and Jahn-Teller distorted lattices.¹³ The actual affair of magnetic phases in these structures is far from clear at present. In this paper, we do not focus our attention to details of magnetic phases, rather we discuss essential features of electrical conduction in these structures. In particular, we aim at understanding of the colossal magnetoresistance observed recently.¹⁻⁴

Let us first construct the following spin-polaron Hamiltonian

$$H = \sum_{\langle ij \rangle, \sigma} t_{ij} c_{i\sigma}^+ c_{j\sigma} + H_L + H_{\text{int}}, \quad (1)$$

where the first term describes the ordinary tight binding band of mobile (itinerant) carriers, the second term represents various magnetic interactions between localized spins, and the last term is the exchange interaction between mobile carriers and localized spins. To proceed we must make some plausible simplifications: (1) The double exchange is strong enough such that the ground state is assumed to be at least locally ferromagnetic (ferromagnetic spin clusters); this is applicable for optimally doped compounds, e.g., $\text{La}_{2/3}\text{Ca}_{1/3}\text{MnO}_3$. (2) The excitations of H_L can be written as a simple magnon spectrum $H_L = \sum_{\mathbf{q}} \omega_{\mathbf{q}} a_{\mathbf{q}}^+ a_{\mathbf{q}}$, where the $a_{\mathbf{q}}$ is the annihilation operator for a magnon with wave vector \mathbf{q} . While we do not include complicated underlying ground states for our system they determine the magnon spectrum

$\omega_{\mathbf{q}}$; this in turn determines the temperature dependence of the resistivity and magnetoresistance. However, it is understood that the magnon spectrum may be quite different from that of ordinary ferromagnetic metals due to the existence of several competing antiferromagnetic couplings in the structure (notice that the undoped material is antiferromagnetic). Therefore, the quasiparticle $a_{\mathbf{q}}^+$ should not be interpreted as a ferromagnetic magnon. (3) This observation leads us to write the interaction between mobile carriers and localized spins as

$$H_{\text{int}} = \sum_{i, \mathbf{q}} K_{\mathbf{q}} e^{i\mathbf{q} \cdot \mathbf{R}_i} (c_{i\uparrow}^+ c_{i\downarrow} + c_{i\downarrow}^+ c_{i\uparrow}) (a_{\mathbf{q}} + a_{-\mathbf{q}}^+), \quad (2)$$

where we have neglected the ordinary non-spin flip interaction $S^z \cdot (n_{i\uparrow} - n_{i\downarrow})$ because the effect of this interaction is to shift the on-site energy for spin up and down mobile carriers. However, one immediately notices that Eq. (2) is different from the usual form of the electron-magnon interaction in a normal ferromagnetic metal which takes the form of $c_{i\uparrow}^+ c_{i\downarrow} a_{\mathbf{q}}^+ + c_{i\downarrow}^+ c_{i\uparrow} a_{-\mathbf{q}}$ as required by spin conservation. For our system, the magnon is understood as an excitation from all competing magnetic interactions as mentioned above. $a_{\mathbf{q}}^+$ is not simply a spin raising operator, rather it contains both creation and annihilation of a spin, similar to an antiferromagnetic magnon or a magnon for a magnetically disordered state. This interpretation is further supported by the experimental fact that the magnetization is smaller than that of fully aligned Mn ions.¹⁻⁴

With these simplifications, we rewrite our model Hamiltonian as

$$H = H_0 + V, \quad (3)$$

where

$$H_0 = \sum_{\mathbf{q}} \omega_{\mathbf{q}} a_{\mathbf{q}}^+ a_{\mathbf{q}} + \sum_{i, \mathbf{q}} K_{\mathbf{q}} e^{i\mathbf{q} \cdot \mathbf{R}_i} (c_{i\uparrow}^+ c_{i\downarrow} + c_{i\downarrow}^+ c_{i\uparrow}) (a_{\mathbf{q}} + a_{-\mathbf{q}}^+) \quad (4)$$

and

$$V = \sum_{\langle ij \rangle, \sigma} t_{ij} c_{i\sigma}^+ c_{j\sigma}. \quad (5)$$

Next, we make a canonical transformation to decouple the magnon and electron parts of the Hamiltonian H_0 , and treat V in Eq. (3) as a perturbation. We choose an S operator

so that the new transformed Hamiltonian $H_0^s = \exp(S)H_0 \times \exp(-S)$ can be written as a sum of magnon and electron Hamiltonian. Such an S is found to be

$$S = \sum_{i\mathbf{q}} (K_{\mathbf{q}}/\omega_{\mathbf{q}}) e^{i\mathbf{q} \cdot \mathbf{R}_i} (c_{i\uparrow}^+ c_{i\downarrow} + c_{i\downarrow}^+ c_{i\uparrow}) (a_{\mathbf{q}}^+ - a_{-\mathbf{q}}). \quad (6)$$

After some straightforward algebra, we find

$$H_0^s = \sum_{\mathbf{q}} \omega_{\mathbf{q}} a_{\mathbf{q}}^+ a_{\mathbf{q}} - \sum_{i,\mathbf{q}} (K_{\mathbf{q}}^2/\omega_{\mathbf{q}}) (n_{i\uparrow} + n_{i\downarrow} - 2n_{i\uparrow}n_{i\downarrow}) \quad (7)$$

and

$$V^s = \sum_{ij} t_{ij} [\cosh(x_i - x_j) (c_{i\uparrow}^+ c_{j\uparrow} + c_{i\downarrow}^+ c_{j\downarrow}) + \sinh(x_i - x_j) \times (c_{i\uparrow}^+ c_{j\downarrow} + c_{i\downarrow}^+ c_{j\uparrow})], \quad (8)$$

where $x_i = \sum_{\mathbf{q}} e^{i\mathbf{q} \cdot \mathbf{R}_i} (K_{\mathbf{q}}/\omega_{\mathbf{q}}) (a_{\mathbf{q}} - a_{-\mathbf{q}}^+)$. The new Hamiltonian $H^s = H_0^s + V^s$ describes the same physical system as the original Hamiltonian. However, H^s has made the perturbation to V^s possible. The magnon part is unchanged by the transformation, while the electron part becomes a Hubbard-like Hamiltonian as evidenced by the $n_{i\uparrow}n_{i\downarrow}$ term in H_0^s . It is this Coulomb term which makes the spin-polaron different from the ordinary polaron Hamiltonian; it becomes a many-body Hamiltonian and cannot be solved exactly. Here we will not further address the effect of the electron-electron interaction, rather we concentrate on the perturbation, Eq. (8).

To obtain the electrical conductivity, one requires a proper treatment of the dynamics of $\cosh(x_i - x_j)$ and $\sinh(x_i - x_j)$. There are two independent processes for the conduction: *elastic* and *inelastic*. For the elastic process the electron transport is described by an effective band with a background of magnons. The effect of this background can be included by calculating the thermal average of $\cosh(x_i - x_j)$ and $\sinh(x_i - x_j)$ in Eq. (8). The inelastic process is that of an electron hopping into its neighbors while absorbing and emitting magnons, i.e., the transport is by incoherent hopping. These two conduction processes have very different temperature dependence. The former is a band description in which the effective mass (inversely proportional to the bandwidth) increases as the temperature increases. This is because the thermal fluctuations of magnons makes the electron hard to move. Thus, the resistivity increases when temperature increases. For the inelastic process, the hopping is assisted by magnons, therefore, this conduction process is favored at high temperatures. We now explicitly write down these two contributions to the conductivity.

For the elastic process, we calculate the thermodynamic averages, $\langle \cosh(x_i - x_j) \rangle$ and $\langle \sinh(x_i - x_j) \rangle$. Since all magnons are assumed to be independent,¹⁴ the thermal average can be done for each magnon frequency. In analog with the conventional polaron problem,¹⁵ we find

$$\langle \cosh(x_i - x_j) \rangle = \exp \left[- \sum_{\mathbf{q}} \left(\frac{K_{\mathbf{q}}}{\omega_{\mathbf{q}}} \right)^2 |1 - e^{i\mathbf{q} \cdot \delta}|^2 (N_{\mathbf{q}} + 1/2) \right] \quad (9)$$

and $\langle \sinh(x_i - x_j) \rangle = 0$, where $\delta = \mathbf{R}_i - \mathbf{R}_j$ is the distance between two nearest Mn sites, and $N_{\mathbf{q}} = [\exp(\beta\omega_{\mathbf{q}}) - 1]^{-1}$ is the number of magnons.

The effective bandwidth of mobile carriers for the elastic process, $\langle t_{ij} \cosh(x_i - x_j) \rangle$, see Eq. (8), depends on temperature through $N_{\mathbf{q}}$; it decreases as the temperature increases. Correspondingly, the effective mass, which is inversely proportional to the bandwidth, increases. The interaction between local spins and mobile electrons leads to an enhancement of the effective mass. Near the transition temperature, the effective mass becomes exponentially large and resistivity can be several orders of magnitude larger than that at low temperatures. If one simply assumes that the metallic conduction is inversely proportional to the effective mass, the conductivity at finite temperature is

$$\sigma(T) = \sigma(0) \exp \left[- \sum_{\mathbf{q}} \left(\frac{K_{\mathbf{q}}}{\omega_{\mathbf{q}}} \right)^2 |1 - e^{i\mathbf{q} \cdot \delta}|^2 N_{\mathbf{q}} \right], \quad (10)$$

where $\sigma(0)$ is the zero temperature conductivity and the factor 1/2 in Eq. (9) has been absorbed in $\sigma(0)$ since it comes from the zero-point motion of magnon.

For *inelastic process*, the conduction will be provided by *incoherent* magnon-assisted hopping, as mentioned before. The conductivity is giving by the Einstein relation

$$\sigma_{in} = ne^2 \delta^2 w / k_B T, \quad (11)$$

where n is the density of mobile carriers, and w is the transition probability which can be obtained by Fermi golden rule, $w = (t^2/\hbar\epsilon) \exp(-\epsilon/k_B T)$, where the activation energy $\epsilon = (1/2) \sum_{\mathbf{q}} (K_{\mathbf{q}}^2/\omega_{\mathbf{q}}) |1 - e^{i\mathbf{q} \cdot \delta}|^2$.

The metallic conduction, Eq. (10), and hopping conduction, Eq. (11), are independent conducting processes. At low temperatures, band conduction dominates while at high temperatures hopping dominates. Here, let us take a simple example where there is only one magnon frequency, $\omega_{\mathbf{q}} = \omega_0$. The conductivity from Eqs. (10) and (11) is

$$\sigma(T)/\sigma(0) = \exp[-\alpha N(\omega_0)] + (b^2/\epsilon k_B T) \exp(-\epsilon/k_B T), \quad (12)$$

where $\alpha = \sum_{\mathbf{q}} K_{\mathbf{q}}^2 |1 - e^{i\mathbf{q} \cdot \delta}|^2 / \psi_0^2$, $b = e \delta t \sqrt{n/\hbar \sigma(0)} \omega_0^2$, and $N(\omega_0) = (e^{\omega_0/k_B T} - 1)^{-1}$. In Fig. 1 we show the resistivity as function of temperature for several plausible values of the parameters. We point out that the peak of the resistivity is not necessary at the Curie temperature as evidenced by the different peak temperatures for different parameters when we hold the magnon frequency constant.

We now briefly comment on colossal magnetoresistance. In our Hamiltonian, the external magnetic field is implicitly included in the magnon frequency $\omega_{\mathbf{q}}$. The variation of the magnon spectrum with the magnetic field is not known at present. If one uses a relation similar to that used in ordinary ferromagnetic metal, i.e., by replacing $\omega_{\mathbf{q}}$ by $\omega_{\mathbf{q}} + g\mu_B H$, we find the magnetoresistance is too small to explain colossal magnetoresistance; this is because $g\mu_B H$ is small compared to intrinsic magnon frequency $\omega_{\mathbf{q}}$ for several Tesla of magnetic field. However, as mentioned in the introduction, the inhomogeneity and various competing magnetic interactions make it plausible for the formation of spin clusters as reported experimentally.¹⁶ In fact, the possibility of spin-

FIG. 1. Resistivity (normalized to $T=0$) as a function of temperature in the absence of magnetic field for three different activation energies $\epsilon=0.12$ eV (upper curve), $\epsilon=0.1$ eV (middle curve), and $\epsilon=0.08$ eV (bottom curve). The parameters are $b=0.1$ eV and $\omega_0=240$ K.

FIG. 2. Resistivity (normalized to $T=0$) as a function of temperature for several values of magnetic fields. We have chosen the cluster size to be ten spins. The parameters are $b=0.1$ eV, $\omega_0=240$ K, and $\epsilon=0.1$ eV.

cluster or giant spins had been modelled by Kasuya.¹² Therefore, one should replace ω_q by $\omega_q + g\mu_B S_c H$, where S_c is the number of spins in spin clusters. In Fig. 2, we show the resistivity as function of temperature for several values of magnetic fields. We notice that the effects of the magnetic field are to suppress the resistivity peak and to push it to higher temperatures. If one assumes the average cluster size to be order of ten spins, one can achieve the colossal magnetoresistance in a few Tesla.

In summary, a spin-polaron Hamiltonian is introduced to study the magnetotransport of doped perovskite compounds. At low temperature, the interaction of mobile carriers with local spins leads to an enhancement of the effective mass of carriers; at higher temperature, the same interaction assists the carrier hopping to nearest neighbor via *inelastic* magnon absorption and emission. Therefore, the metal-insulator transition in the conductivity is a natural result of our Hamiltonian. When we apply our theory to calculate magnetoresistance, we find that most of the experimental features can be explained *as long as* we rely on the existence of spin clusters. Details of the effects of the spin cluster on magnetization and domain boundaries scattering will be published elsewhere.

Response to an electric field of $\text{Nd}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$ films in a MOSFET configuration (abstract)

S. B. Ogale, V. Talyansky, G. C. Xiong, R. P. Sharma, R. Ramesh, R. L. Greene, and T. Venkatesan

The effect of an electric field on GMR oxide films was studied in a MOSFET configuration where the gate dielectric was a layer of SrTiO_3 epitaxially grown on an underlying layer of the manganate which served as the source/drain. The response of the manganate channel was studied for different gate voltages. The following significant features were observed. The peak resistance temperature shifted to lower temperature for both polarities of the field. The resistance change varied quadratically with the field indicating the dominance of strain or polarization effects. In dynamical studies of the system using the gate voltage as an excitation the system showed anomalous slowing down near the peak of the resistivity. These results are understood on the basis of a stress effect on the film due to electro-elastic effects in the SrTiO_3 layer, which introduces a tensile stress in the manganate layer upon the application of a gate voltage. The anomalous slowing down of the system near the ferromagnetic phase transition suggests a strong coupling between the spins, transport and structural distortions in the system. © 1996 American Institute of Physics.

Magnetotransport and hysteretic behavior in epitaxial $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3-\delta}$ films

C. L. Canedy, K. B. Ibsen, and Gang Xiao^{a)}

Department of Physics, Brown University, Providence, Rhode Island 02912

J. Z. Sun, A. Gupta, and W. J. Gallagher

IBM Research Division, Yorktown Heights, New York 10598

We have fabricated epitaxial $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3-\delta}$ thin films using pulsed laser deposition and performed subsequent thermal treatments. Magnetoresistance values as large as 14 000% ($\Delta\rho/\rho_H$) were obtained. Above magnetic ordering temperatures, we observed a thermally activated conductivity that also has a quadratic magnetic field dependence. At low temperatures, we found a large hysteresis in the magnetoresistance that correlates with an unusual magnetic hysteresis curve. We interpret the hysteretic behavior as the result of a “frozen-in” canted spin structure. Our results suggest that the electron conduction in this material is most sensitive to the canting angle of the neighboring Mn spins. © 1996 American Institute of Physics. [S0021-8979(96)49008-5]

Sparked by the recent discovery of “colossal” magnetoresistance (CMR)^{1,2} the perovskite (La-A)MnO₃ system (A = Ca, Ba, Sr, or Pb) has witnessed a resurgence of the work started back in the 1950's.^{3,4} It is fascinating that the magnetoresistance can be as large as 100-fold in polycrystalline bulk materials⁵ and 1000-fold in epitaxial thin films.² Recently, phenomenal values of MR, in excess of one-millionfold, were observed in the antiferromagnetic $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ compound.⁶ The underlying mechanism for CMR remains unsettled, but it is clear that it is of a different origin than that of the giant magnetoresistance (GMR) effect observed in many metallic layered^{7,8} or granular structures.⁹ With the freedom of varying doping level (x) and oxygen content (δ), the $\text{La}_{1-x}\text{A}_x\text{MnO}_{3+\delta}$ system can develop diverse types of magnetic orderings, ranging from the layered antiferromagnetic (AFM) parent phase, to a canted spin structure, a ferromagnetic phase, and finally to the alternating AFM state.³ Associated with these magnetic structures is the rich magnetotransport behavior, of which the CMR is one of the most interesting.^{1,2,5,6} The extreme sensitivity of the electron transport to the underlying magnetically static and dynamic states can be traced to the intimate coupling between the charge carriers and the local spin structure. In this perovskite system, not only do the doped carriers participate in the electrical conductivity, but they are also responsible for the magnetic ordering, a mechanism commonly dubbed as double exchange.¹⁰⁻¹³

The effect of CMR is most pronounced at temperatures near the ferromagnetic ordering temperature (T_c).^{1,2,5,6} For low T , the value of resistivity decreases rapidly with decreasing T . At high T , resistivity decreases with increasing T . A study focused on the high- T region above T_c provides useful information about the electron transport in a disordered magnetic state. On the other hand, the low- T region (e.g., 4.2 K) provides an ordered magnetic state free of thermal excitations (magnons, phonons, etc.), allowing one to probe the correlation between the electron transport and the static magnetic structure. In this work, we present results obtained from

the $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3+\delta}$ thin films both in the high- and low- T regions. We have observed different field-dependent characteristics of resistivity in these two regions. The thermally activated resistivity persists to a high T of about 500 K. In the low- T region, an unusual type of magnetic hysteresis loop leads to a corresponding MR with a large hysteresis. We attribute the origin of the hysteresis to a glassy canted-spin structure. Our results point to a strong coupling between the electron motion and the local spin orientations.

Thin films were grown from a sintered ceramic target of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ using pulsed laser deposition. The oxygen pressure during ablation was 300 mTorr. The substrates, single crystal (100) SrTiO₃, were kept at a temperature of 700 °C. The deposition rate was about 0.5 Å pulse, and the laser power density around 3 J/cm². The film thickness is about 1000 Å. X-ray diffraction patterns of these films showed intense and sharp (00 n) peaks, indicating (001) oriented growth. Magnetization measurements were performed in a Quantum Design SQUID magnetometer. For magnetotransport measurements, the samples were patterned into Hall bars using the standard photolithography and ion-beam etching. Platinum was deposited onto contact pads on which wires were attached with the help of a wedge bonder. Four-probe transport measurements were then carried out in a cryostat equipped with an 8 T magnet.

We focus on the results of two $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3+\delta}$ films (L011 and L012), that were subjected to a postdeposition thermal treatments at 850 °C for 0.5 h in either an oxygen (L011) or argon atmosphere (L012). The oxygen content in the films was not determined. However, it is expected to be different for the two samples. Shown in Fig. 1 is the T dependence of resistivity $\rho_0(T)$ and $\rho_8 T(T)$ measured in zero and an applied 8 T magnetic field (H), respectively. The peak of $\rho_0(T)$ occurs near T_c which is determined from the initial susceptibility $\chi(T)$ vs T curve. The T_c values of the two samples (L011 and L012) are about 140 and 204 K, respectively. Above T_c , $\rho_0(T)$ exhibits a thermal activation behavior with an activation energy of 0.12 eV for L011 and 0.10 eV for L012. This behavior persists up to at least 500 K. Between 500 K and our maximum measurement T of 600 K, $\rho_0(T)$ starts to increase slightly with T for sample L012,

FIG. 1. The temperature dependence of resistivity, $\rho_0(T)$ and $\rho_8(T)$, measured in zero magnetic field and an applied field of 8 T for two $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3-\delta}$ thin films, L011 (top) and L012 (bottom) annealed under different conditions. Also shown is the corresponding magnetoresistance ratio $[\rho_0(T) - \rho_8(T)]/\rho_8(T)$ vs T .

which could be an indication that the electron-phonon interaction starts to dominate the transport. Figure 1 also shows the MR ratio, defined as $[\rho_0(T) - \rho_8(T)]/\rho_8(T)$, as a function of T . The sample L011 with a lower T_c has a maximum MR of about 14 000%, whereas L012 has a maximum MR of about 2300%. This is consistent with the general observation that samples with a lower T_c tend to have a larger MR.

We have also measured resistivity $\rho(H)$ as a function of H at various T 's between 4.2 and 300 K. The results are shown in Fig. 2. When $T > T_c$, the conductivity $\sigma(H)$ shows a quadratic dependence on H , i.e., $\sigma(H) = \sigma_0 + \sigma_1 H^2$. As T approaches and then is lowered below T_c , a different H dependence of $\rho(H)$ emerges. Most interestingly, at a sufficient low T , $\rho(H)$ develops an anomalous hysteretic behavior between the unmagnetized and the magnetized states. When a sample is initially magnetized, a large and primarily negative MR appears up to our maximum field of 8 T. Then as H is reduced, a large deviation in $\rho(H)$ sets in and the $\rho(H)$ curve becomes much flatter. Further H cycling between ± 8 T yields a much smaller MR with only a tiny hysteresis. It is surprising that the large hysteresis between the initial and the subsequent magnetizing processes could persist up to a field as large as 8 T. This hysteresis is most pronounced at low- T .

Since the magnetotransport of this system is strongly correlated with the magnetization,¹⁴ we have subsequently

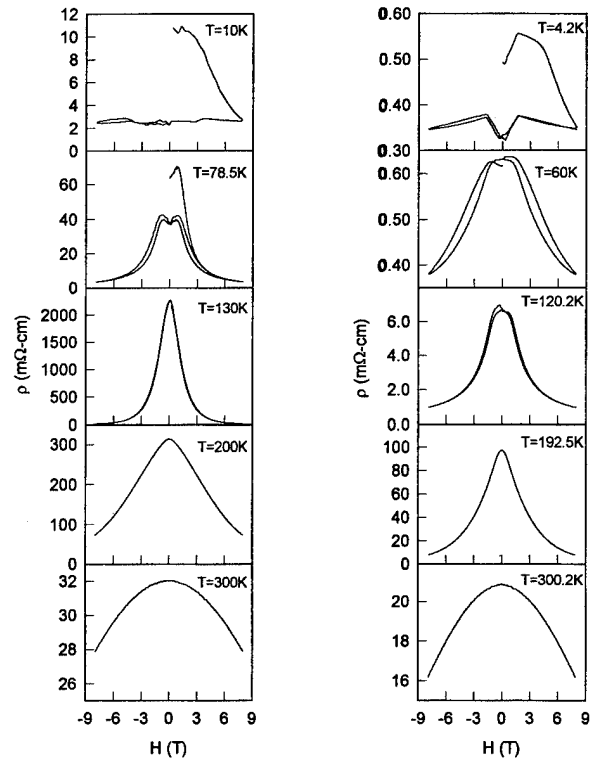

FIG. 2. The field dependence of resistivity $\rho(H)$ measured at various temperatures for the L011 (left) and L012 (right) thin films. Note the large hysteresis (up to 8 T) at a low T between the initial and the magnetized state.

measured the magnetic hysteresis loop as shown in Fig. 3 for sample L011. Indeed an intimate correspondence between $M(H)$ and $\rho(H)$ is revealed. Starting from the unmagnetized state (i.e., the virgin state) the $M(H)$ curve shows a rapid

FIG. 3. The anomalous magnetic hysteresis curve for the L001 thin film measured at 5 K. The arrows indicate the magnetizing sequence. Arrow 1: starting from the unmagnetized state; Arrows 1-2-3-4, cycling field from +5.5 to -5.5 T and back to +5.5 T. Note the correspondence between the hysteresis in $M(H)$ shown here and that in $\rho(H)$ at a low T shown in Fig. 2 for the L001 sample.

increase in M within a couple of kG, and then a more gradual increase in M with H (see arrow 1) up to 5.5 T. The subsequent H cycling (arrows 2-3-4-5) leads to a loop where $M(H)$ is always larger than the initial $M(H)$, and where $\rho(H)$ much less than the initial $\rho(H)$. Without the initial curve (arrow 1), the loop is of the type of a soft ferromagnet with small hysteresis. It is the large hysteresis persisting to a very high field that makes the magnetizing process highly unconventional. Comparing the low- T data in Figs. 2 and 3, one observes that $\rho(H)$ and $M(H)$ share a similar hysteretic behavior.

A study of the correlation between $\rho(H)$ and $M(H)$ and their hysteresis at low T may shed light into the transport process. Because of the negligible thermal disturbances at low T , the magnetotransport is mostly dependent on the static magnetic structure. Based on the observations from Figs. 1 and 2, a couple of qualitative comments can be made.

(1) The unmagnetized state has a canted ferromagnetic structure as indicated by the high- H susceptibility in the first $M(H)$ curve. This is consistent with the double exchange model that predicts a stable canted spin arrangement under the influence of doped carriers.¹¹⁻¹³ However, the high- H susceptibility should not be hysteretic if the carriers are truly delocalized. Moreover, the canting angle should depend on H in a unique and reversible fashion (following states with minimized free energies).¹² However, experimentally the canting angle seems to have a memory of its value at high H even after H is released. This is reminiscent of a glassy magnetic state, having many H -dependent local free energy minima that can trap the local spin distortions. For this glassy state to exist, the carriers cannot be completely delocalized. Otherwise one would expect the "frozen" spin state to relax to the global energy minimum rapidly. If the above scenario is indeed valid, it would be more appropriate to treat the doped carriers as not being completely free. In fact even at $T=4.2$ K, these materials are rather poor metals having resistivities in the range of a few m Ω cm, over three to four orders of magnitude larger than that of a typical metal.

(2) The correlation between $\rho(H)$ and $M(H)$ is again consistent with the double exchange mechanism.¹⁰⁻¹³ A par-

allel spin arrangement facilitates transfer of carriers from one site to the other, whereas an antiparallel configuration would block the carrier motion. The application of a field on the unmagnetized state tends to align the spins, hence, improving the electrical conductivity. When the field is reduced, the spin system retains memory of its high- H configuration, therefore, the conductivity becomes less dependent on H as seen in the low- T data in Fig. 2.

In summary, we have observed an anomalous low- T hysteretic behavior in $\rho(H)$ and $M(H)$ in the ferromagnetic $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_{3+\delta}$ system. This large hysteresis which persists to a very high H (8 T in our setup) may be caused by a glassy type of local spin structure. It is likely that the carriers are somewhat localized in the unmagnetized state. An application of H allows the carriers to diffuse with increasing ease. In the high- T region, we found that thermally activated transport persists to about 500 K, and that the conductivity exhibits a quadratic H dependence.

Epitaxial thin films of $\text{La}_{1-x}\square_x\text{MnO}_{3-\delta}$ ($0 \leq x \leq 0.33$) where \square is a vacancy have been grown on (100) SrTiO_3 substrates by pulsed laser deposition. The lanthanum deficiency results in self doping of the system without the need for divalent ion substitution. Both the films and the bulk targets used for deposition were ferromagnetic and showed giant magnetoresistance (GMR). The films increased in saturation magnetization M_s and Curie temperature T_c with increasing x . The T_c , however, was about the same as found in Ca_x substitutions. Bulk samples showed little change in M_s and T_c with vacancy concentration. M_s in bulk samples is about half the value found in the films which have theoretical saturations for $x > 0.2$. GMR in the films is a few hundred percent but the bulk values are 25% at $H = 1.8$ T. © 1996 American Institute of Physics. [S0021-8979(96)49108-1]

I. INTRODUCTION

Oxide films of manganese with the formula $\text{La}_{1-x}\text{A}_x\text{MnO}_3$, where A is a divalent ion, are ferromagnetic over a wide compositional range and have been shown to exhibit a giant magnetoresistance (GMR). Films in particular have large GMR. Jin *et al.*,^{1,2} find that films of La-Ca-Mn-O can have GMR of over 100 000%. Bulk polycrystalline samples have smaller GMR but recently Tokura *et al.*³ report on bulk single crystals of La-Sr-Mn-O which have a GMR of several hundred percent.

LaMnO_3 has the perovskite structure and it is an antiferromagnetic insulator. The divalent substitution for La maintains the perovskite structure but causes the normally Mn^{3+} to change to Mn^{4+} . This results in conductivity as well as ferromagnetic exchange interactions between the Mn^{3+} and Mn^{4+} which was suggested to be Zener double exchange.¹ In our study we form $\text{La}_{1-x}\square_x\text{MnO}_{3-\delta}$ where \square_x represents x atomic fraction vacancies having zero valence and thus is self doping. The doping should vary linearly with x , having all Mn^{3+} at $x = 0$ and all Mn^{4+} at $x = 0.33$, if the oxygen stoichiometry is held constant ($\delta = 0$). No direct measurement of oxygen content was made.

Thin films of $\text{La}_{1-x}\square_x\text{MnO}_{3-\delta}$ were made by pulsed laser ablation⁴ from bulk target samples. Targets of $\text{La}_{1-x}\text{MnO}_{3-\delta}$ with varying ratios of La/Mn, were prepared from powders obtained by reaction of the high purity component oxides La_2O_3 and MnO at 1050 °C. High density (>95%) targets were obtained by isostatic pressing of the prepared powders and subsequent sintering for 0.1–0.5 h at 1550 °C in air. Powder x-ray diffraction indicated that the targets have single-phase orthorhombically distorted perovskite structures which index to $\text{LaMnO}_{3.00}$.

Films ~1000-Å thick were deposited on SrTiO_3 substrates held at 700 °C. After deposition the films were cooled to room temperature in 700 Torr oxygen. X-ray diffraction measurements of the films showed a small but systematic decrease in lattice parameter with increasing x consistent with the formation of mixed valence $\text{Mn}^{3+}/\text{Mn}^{4+}$.⁵

The electrical resistance and MR were measured as a function of magnetic field using a four probe technique.

Magnetization studies were made using a Quantum Design SQUID magnetometer over a temperature range of 5–360 K. We have investigated both the film and the bulk target samples of this vacancy doped system.

II. RESULTS AND DISCUSSION

Figures 1 and 2 show the magnetic data of the films and target samples, respectively. Because of the wide range of resistivity ρ and MR, these data are listed in Table I. Films are 1 cm×0.5 cm rectangles and both magnetic moments M and ρ are measured on the same rectangular sample. The bulk samples are cut in two sizes for convenience on M and ρ measurements.

Saturation magnetic moments for the film are plotted in volume units and roughly increase from 340 to 480

FIG. 1. Saturation magnetic moment M in fields of 4 T and Curie temperature T_c for $\text{La}_{1-x}\square_x\text{MnO}_{3-\delta}$ films. The value of T_c are within ± 10 K. The filled data points for $x = 0.25$ are for an annealed sample. Dashed line AB is calculated M for all Mn moments aligned parallel. Dashed curve CD are T_c for $\text{La}_{1-x}\text{Ca}_x\text{MnO}_{3-\delta}$ from Ref. 6.

FIG. 2. Saturation magnetic moment σ at 4 T for the bulk target samples of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_{3-\delta}$. Curie temperatures are within ± 10 K. The filled data points at $x=0$ are for an annealed sample.

(emu/cm³) with increasing vacancy concentration as shown in Fig. 1. The dashed line marked (AB) on Fig. 1 is a calculated M based on all $\text{Mn}^{3+}/\text{Mn}^{4+}$ magnetic moments aligned parallel and using densities of 6.6 gms/cc at $x=0$ reduced to 5.3 gms/cc at $x=0.33$ due to the vacancy concentration. Comparing the data points with the calculated values M increases with x and has parallel alignment of $\text{Mn}^{3+}/\text{Mn}^{4+}$ for $x>0.2$. There is a corresponding increase in Curie temperature T_c with x . As seen in Table I, resistivity for films decrease with x , an effect also observed by Ju *et al.*,⁶ for the $\text{La}_{1-x}\text{Sr}_x\text{MnO}_z$ system. Our magnetic measurements for $\text{La}_{1-x}\text{Sr}_x\text{MnO}_{3-\delta}$ are compatible with an increase in the number of Mn^{4+} ions but it is not clear that we have reached all Mn^{4+} at $x=0.33$ which is expected to be an insulator. The maximum MR for the films as listed in Table I decreases with increasing x which means that MR is smaller in films with high T_c . The last column of Table I lists the temperature at which approximately maximum GMR is found and this is in the region of the Curie temperature for the various compositions.

As shown in Fig. 1, the film for $x=0$ which might be expected to be antiferromagnetic has a ferromagnetic com-

0.20	107	96	12	100
0.33	440	350	26	115

^aAnnealed.

Resistivity $\rho(0)$ is at $H=0$ and $\rho(1.8)$ is for $H=1.8$ T. $\text{GMR}=[\rho(0)-\rho(1.8)]/\rho(1.8)$. $T(\text{GMR})$ is temperature for listed GMR estimated to be at maximum value of GMR for $H=1.8$ T.

ponent possibly due to a canted arrangement of Mn moments. Any canted atomic moments of the Mn disappears for $x>0.2$. The two filled data points for $x=0.25$ represent a sample annealed in oxygen at 850 °C for 30 min. There is a small increase in T_c and M for the annealed sample. The dashed line CD follow T_c values given for $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$.⁶ Note that we use x regardless of the valency represented but there is little difference in T_c between Ca_x and \square_x .

The bulk data shown in Fig. 2 also indicate that the $x=0$ sample has ferromagnetic character but similar to the film values the M and T_c are depressed. After annealing in oxygen at 850 °C for several hours both M and T_c increase as shown by the filled data points at $x=0$. Figure 2 illustrates that M and T_c decrease slightly with increasing x which is opposite in behavior to the films. From Table II we note that there is a sharp increase in ρ with x and that MR at $\sim 25\%$ is much smaller than found in the films. It would appear that the almost constant value of M and T_c with high ρ mean that not much Mn^{4+} is present in the bulk samples or at least the concentration of Mn^{4+} remains constant with x .

The values of M (bulk) range from 40 to 50 emu/gm close to one-half that of the films if the theoretical densities mentioned previously are used to calculate film moments in emu/gm. The low values of M and T_c , also the high ρ for the bulk samples, are further evidence of weak double exchange because of low Mn^{4+} concentration. We have determined the intrinsic value of the Mn moment in the bulk sample from measurements of the paramagnetic susceptibility χ above T_c by fitting the data to a Curie-Weiss law $\chi_M = C_M/(T - \theta)$ where χ_M and C_M are molar values. We find for $x=0$ (as deposited $C_M \approx 3.38$, $\theta \approx 70$ K; $x=0$ (anneal) $C_M \approx 3.06$, $\theta \approx 133$ K; $x=0.2$, $C_M \approx 3.06$, $\theta \approx 115$ K and $x=0.33$, $C_M \approx 2.74$, $\theta \approx 122$ K. Experimental values of C_M reported for Mn^{3+} range from 2.89 to 3.01 ($\mu_{\text{eff}} \approx 4.9$) while Mn^{4+} has $C_M \approx 1.82$ ($\mu_{\text{eff}} \approx 3.9$).⁷ It therefore appears that Mn^{3+} is dominant in the bulk samples for all values of x with possibly only 5% Mn^{4+} . Stoichiometry of the oxygen must compensate for the vacancy concentration. The paramagnetic measurements have two interesting features. First, there is a Curie-Weiss law behavior with C_M values representative of Mn^{3+} with some Mn^{4+} , and second, there is good agreement of the θ intercept with T_c . This means the exchange interactions stay constant with temperature in the bulk samples and that they are homogeneous magnetic materials. The low concentration of Mn^{4+} believed to exist in these target samples place a limit on extending the above interpretation to high conductivity film samples which have a larger Mn^{4+} concentration.

FIG. 3. Resistivity for film $x=0.25$ as a function of temperature at applied fields 0–4 T. The MR in the temperature range, 240–250 K is over 400% for $\Delta H=4$ T.

The resistivity values obtained in fields of 1.8 T are shown in Tables I and II. In Fig. 3 are shown results for the $x=0.25$ film made in a superconducting magnet system with fields from 0 to 4 T and temperatures from 5 to 350 K. It shows clearly the effect of the magnetic field on the resistivity with maximum ρ moving to high temperature for increased H . In Fig. 4 we plot ρ vs H and M for a constant temperature of 240 K in the region of maximum MR for the $x=0.25$ sample of Fig. 3. Approximately ρ is linear over this limited range of M indicating that scattering of the conduction carriers by the Mn moments is the dominant feature. How ρ changes with M and H as a function of temperature has been discussed by Tokura *et al.*³ for La-Sr-Mn-O and Hundley *et al.*⁸ for La-Ca-Mn-O.

Based on the scattering behavior and the paramagnetic Curie-Weiss susceptibility our description of the MR in

FIG. 4. Resistivity ρ as a function of H and M for film sample shown in Fig. 3 at a fixed temperature of 240 K.

these materials would agree with that given by Tokura *et al.*³ Namely, that spin polarized conduction carriers become prominent in the region of T_c as the spontaneous magnetic order increases but there remains large scattering from still disordered Mn moments. As the Mn disorder is reduced by either lowering the temperature or applying a magnetic field the resistivity decreases as illustrated in Fig. 3.

Superparamagnetic behavior and giant magnetoresistance in oxygen deficient $R_{0.67}Sr_{0.33}MnO_z$ ($R=Nd, Pr$) epitaxial films (abstract)

H. L. Ju, Qi Li, G. C. Xiong, T. Venkatesan, and R. L. Greene

Center for Superconductivity Research, Department of Physics, University of Maryland, College Park, Maryland 20742

We have studied the magnetic and magnetotransport properties of oxygen deficient $R_{0.67}Sr_{0.33}MnO_z$ ($R=Nd, Pr$) films and have observed superparamagnetic behavior in these films. The superparamagnetism is indicated by (i) the increasing spread between zero field cooled (ZFC) and field cooled (FC) magnetization curves as temperature decreases, (ii) a sharp drop of the ZFC magnetization at low temperature, (iii) enhanced Curie-Weiss constant above the ferromagnetic temperature, and (iv) at low temperature a sharp drop of coercivity (H_c) with increasing temperature. These findings strongly suggest that all oxygen deficient manganites are magnetically inhomogeneous; i.e., ferromagnetic clusters exist. We estimate the spin cluster diameter to be 7–10 nm at low temperature ($T<30$ K). We discuss a possible origin of the giant magnetoresistance effect based on the existence of spin clusters. © 1996 American Institute of Physics. [S0021-8979(96)59108-5]

Role of lattice distortions in the transport property of $R_{0.7}Me_{0.3}MnO_3$ ($R=Pr, Nd, La$ and $Me=Ba, Sr, Ca$) (abstract)

R. P. Sharma, G. C. Xiong, S. B. Ogale, R. L. Greene, and T. Venkatesan

University of Maryland, Center for Superconductivity Research, College Park, Maryland 20742

There are different models which try to explain the transport properties of the manganese oxides in terms of magnetic polarons, Zener double exchange and Jahn-Teller distortions of the lattice which is temperature dependent. Using Rutherford backscattering techniques (2–3 MeV He ions) we are measuring the presence of lattice distortions by studying the angular scans in the channeling mode. The angular widths (FWHM) can be used to extract both dynamic and static displacements of the atoms from their equilibrium sites. The technique is extremely powerful in the sense that *local uncorrected* displacements as small as 0.01 Å from the equilibrium position can be detected. The extraction of the physics from the data is relatively straight forward compared to other techniques such as XRD or neutron scattering. Using a variable temperature backscattering system at our center (one of three or four systems around the world) the angular width (FWHM) is found to exhibit a dramatic change with temperature increasing with decreasing temperature showing a possible correlation with both the transport and magnetic properties. The results suggest a decrease in the lattice disorder with reduced temperature far in excess of what one would predict on the basis of a simple Debye behavior. The reduction in the lattice disorder correlates very well with the resistance vs temperature dependence. A variety of manganese oxide epitaxial thin films grown by pulsed laser deposition have been studied and the data suggests a role for structural distortions in any mechanism to explain the transport properties of these materials. © 1996 American Institute of Physics. The effect of disorder and fluctuations on the magnetotransport of a double-exchange ferromagnet (abstract)

Jeff M. Byers

Naval Research Laboratory, Washington, D. C. 20375

The discovery of colossal magnetoresistance (CMR) in the doped perovskite manganites has reawakened interest in the double-exchange mechanism proposed to Zener. To account for the close relation between ferromagnetism and metallic transport in lanthanum manganites doped with divalent cation (Ca, Sr, Ba) Zener claimed that an electron could delocalize on lattice of spins and still conform to Hund's Rule if a ferromagnetic coupling between spins were mediated by that same electron. Thus, the onset of metallic behavior (delocalization) is intimately linked to ferromagnetic ordering of the spin lattice. Clearly, the double-exchange mechanism provides some necessary physics but is not sufficient in explaining the key mystery of the CMR materials: What causes the large peak in the resistivity vs. temperature and why is it removed by an applied magnetic field. The effect of disorder and fluctuations on the double-exchange mechanism may provide the answers. Several sources of disorder in these materials act to form a mobility edge via Anderson localization: intrinsic divalent/trivalent cation disorder, off-diagonal disorder caused by the spin lattice and oxygen vacancy disorder. A mean-field calculation reveals that below the Curie temperature those carriers aligned opposite to the magnetization experience a narrowing band as the temperature is reduced. Fermi glass behavior is induced in this minority carrier band by the Fermi level falling below the mobility edge. However, the mean-field result does not contain a peak in resistivity since the majority carrier band does not behave as a Fermi glass and effectively "shorts out" the more resistive minority conduction channel. The formation of the resistivity peak requires the inclusion of ferromagnetic fluctuations above the Curie temperature that tend to "mix" the two conduction channels. The application of a magnetic field unmixes the conduction channels once again allowing the carriers aligned with the magnetization to carry current solely in the low-resistance channel (causing the dramatic negative magnetoresistance). Ozone assisted, block-by-block, molecular beam epitaxy of La-M-Mn-O (M=Ca,Ba,Sr) thin films and La-M-Mn-O/Dy-Ba-Cu-O multilayers (abstract)

V. A. Vas'ko, P. A. Kraus, V. S. Achutharaman, C. A. Nordman, and A. M. Goldman

Center for the Science and Application of Superconductivity and School of Physics and Astronomy, University of Minnesota, Minneapolis, Minnesota 55455

We report the growth of thin (<100 nm) La-M-Mn-O (M=Ca,Ba,Sr) films by ozone assisted, block-by-block, molecular beam epitaxy on single crystal SrTiO₃, and LaAlO₃, substrates. The films were characterized by RHEED, high resolution x-ray diffraction, x-ray reflectivity, RBS, Ion channeling, SEM, and STM. These films show a very high degree of crystalline perfection as evidenced by very low rocking curve widths (<0.06 deg), extremely low surface roughness (of the order of one unit cell) and the observation of thickness fringes using x-ray diffraction. Careful magnetic, transport and magnetotransport measurements of these films will be presented. Multilayer structures of La-M-Mn-O and Dy-Ba-Cu-O/La-Sr-Cu-O superconductors have also been fabricated. The effect of interfacial chemistry on the transport properties of such layers and the compatibility issues for the growth of manganate/cuprate superconductor multilayers will be discussed. © 1996 American Institute of Physics. Single crystals of $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$ with x ranging from 0.06 to 0.42 have been investigated by various techniques: resistivity and magnetoresistance, superconducting quantum interference device magnetometry, and ^{55}Mn nuclear magnetic resonance. In addition, for two Sr concentrations, $x=0.13$ and 0.25 , the $I(V)$ characteristic of the oxide-metal junction has been measured versus temperature. Semiconductor-metal transition occurring just below the Curie temperature T_c was observed for $x \geq 0.175$ whereas, for $x \leq 0.15$, the crystals exhibits only semiconducting behavior, in agreement in the previous studies.¹ These transport properties are closely connected with the electron transfer mediated by the double exchange interaction between Mn^{3+} and Mn^{4+} , as revealed by ^{55}Mn spin-echo experiments. A cusp in the magnetoresistance (MR) was observed near T_c for the crystals with $x \geq 0.13$ with typical maximum resistivity ratio $R(0)/R(10\text{ T}) \approx 10$; for the sample with $x=0.1$, the huge MR persists well below $T_c \approx 140\text{ K}$, which is probably due to a noncollinear spin configuration. The $I(V)$ characteristic of the oxide-aluminum junction is strongly dependent on temperature and applied magnetic field. In the semiconducting phase, a nonlinear behavior reminiscent to that of a strongly doped dirty semiconductor is observed. © 1996 American Institute of Physics. [S0021-8979(96)81408-0]

Density-functional studies of the electronic structure of the perovskite oxides: $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$

S. Satpathy

Department of Physics and Astronomy, University of Missouri, Columbia, Missouri 65211

Zoran S. Popović and Filip R. Vukajlović

Laboratory for Theoretical Physics, Institute of Nuclear Sciences- "Vinča", 11001 Belgrade, Yugoslavia

Using density-functional methods, we study the electronic structures of the lanthanum-based "double-exchange" perovskite magnets. Antiferromagnetic insulating solutions are obtained for both the end members, LaMnO_3 and CaMnO_3 , within the local density approximation (LDA), with the Jahn-Teller (JT) distortion of the oxygen octahedron taken into account. The JT distortion splits off the $\text{Mn}(3d)e_g$ bands producing an energy gap within the LDA, with the bands derived from the (z^2-1) orbital, pointed along the long basal-plane Mn—O bond, occupied and the (x^2-y^2) bands empty. The on-site Coulomb repulsion and the intra-site exchange terms are found to be, respectively, $U \approx 8-10$ eV and $J \approx 0.9$ eV, from the "constrained" density-functional theory. The large value of U as compared to the bandwidth indicates that the manganese perovskite oxides are strongly correlated systems. © 1996 American Institute of Physics. [S0021-8979(96)49208-8]

The hole-doped manganese perovskite oxides, such as $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$, are prime examples of solids with a ferromagnetic conducting state caused by the "double exchange" mechanism, where the magnetic coupling between localized spins on neighboring atoms is mediated via conduction electrons.¹⁻⁴ Both the end-members, LaMnO_3 and CaMnO_3 , are antiferromagnetic (AF) insulators with, respectively, Mn^{3+} ($t_{2g}^3e_g^1$) and Mn^{4+} ($t_{2g}^3e_g^0$) configurations of the Mn ions. The localized spins of the t_{2g} electrons are coupled ferromagnetically by the doped holes in the partially filled e_g band introduced by the Ca atoms. Thus, the partially filled e_g band is responsible simultaneously for ferromagnetism and conduction in the solid. This is precisely what is experimentally observed, viz., that the mixed valence compound $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ shows the highest electrical conductivity for $0.2 \leq x \leq 0.4$, exactly in the concentration range where the material is ferromagnetic.⁵ New interest on these systems has been revived by the recent discovery of colossal magnetoresistance (CMR) in the La-Ca-Mn-O films.^{6,7}

In this paper, we examine the electronic structure of the two end members, LaMnO_3 and CaMnO_3 , from density-functional band calculations using the local spin-density approximation (LDA), as well as the "constrained" density-functional and the "LDA+U" theories.⁸

Both LaMnO_3 and CaMnO_3 form in the orthorhombic crystal structure⁹ which is a distorted form of the cubic perovskite structure. While in the Ca compound, the distortion of the O octahedra surrounding the manganese atoms is largely absent, in the La compound, the octahedra are distorted significantly with three distinct Mn—O bond lengths. The Jahn-Teller (JT) distortion of the O octahedron is understandable in view of the $t_{2g}^3e_g^1$ configuration of the Mn ion. In addition to the JT distortion, there is a slight rotation of the octahedra, which is neglected in the calculations reported here. All our calculations reported here were performed using the linear muffin-tin orbitals (LMTO-ASA) method¹⁰ and the ideal tetragonal crystal structure for the two perovskites

with inclusion of the JT distortions. Thus, the magnetic unit cell in our calculation has four formula units for LaMnO_3 and two for CaMnO_3 .

The antiferromagnetic band structures of LaMnO_3 and CaMnO_3 are shown in Fig. 1. The observed AF order, type A for the former and type G for the latter compound,¹¹ is reproduced from the local-density calculations. The key features of the AF band structures agree with the independent LAPW calculations of Pickett and Singh.¹² As seen from Fig. 1, the key orbitals near E_f are the O(2p) and Mn(3d) orbitals with the energy gap occurring in the middle of the Mn(3d) bands. The outer electrons from the La, Ca, and Mn atoms are transferred to complete the 2p shell of the oxygen atoms, resulting in the nominal chemical formulas of $\text{La}^{3+}\text{Mn}^{3+}\text{O}_3^{2-}$ and $\text{Ca}^{2+}\text{Mn}^{4+}\text{O}_3^{2-}$, respectively.

We have studied the effect of the Jahn-Teller distortion of the cubic octahedra on the band structure by performing a series of calculations for LaMnO_3 with various amounts of the distortion. There are three types of distortions¹³ affecting the Mn—O bond lengths: (i) The breathing mode (Q_1), (ii) the basal-plane distortion mode (Q_2) with one diagonally opposite O pair displaced outwards and the other pair displaced inwards, and (iii) the octahedral stretching mode (Q_3) where the four in-plane O atoms are displaced inwards and the two apical O atoms are displaced outwards. The amplitudes of these three modes in LaMnO_3 are, respectively, 0.08, 0.20, and 0.11 Å, resulting in the three distinct Mn—O bond lengths: 1.91, 2.19, and 1.96 Å. We find that the basal-plane distortion mode Q_2 is the most effective in splitting up the e_g bands in LaMnO_3 thereby producing an energy gap, and that the Q_1 or the Q_3 distortions are relatively ineffective in opening up the gap. We find that a JT distortion of the Q_2 type, with the oxygen atoms displaced by at least the amount ≈ 0.1 Å from their ideal positions, is necessary to produce a band gap in LaMnO_3 . In the crystal, the measured value of this distortion is about 0.15 Å, which is therefore enough for the insulating solution. The t_{2g} bands in contrast remain more-or-less unaffected by the distortions.

The splitting of the Mn(3d) bands in LaMnO_3 due to the

FIG. 1. Electronic band structures of antiferromagnetic LaMnO_3 and CaMnO_3 in the ideal tetragonal structure with, respectively, type A and type G magnetic configurations. The Jahn-Teller distortion of the oxygen octahedra was included for LaMnO_3 . The symmetry components e_g and t_{2g} correspond to the $\text{Mn}(3d)$ orbital, and spin components (\uparrow or \downarrow) are local to individual atoms. Energies are with respect to E_f .

combined effects of the cubic crystal field, exchange, and the Jahn-Teller distortion as obtained from our calculations has been shown in Fig. 2. The exchange splitting is about 3.0 eV which removes the minority-spin bands up above E_f . The cubic crystal-field splitting between the t_{2g} and the e_g orbitals is about $\Delta_{cf} \approx 2.0$ eV, while the Q_2 distortion of the oxygen octahedron splits the e_g bands by $\Delta_{JT} \approx 1.5$ eV. The total band width of the occupied $\text{Mn}(3d)$ bands is about 2.4 eV. Of this, the t_{2g} bands are 1.3 eV wide, while the Jahn-Teller split e_g^1 band just below E_f has a width of about 1.6 eV.

We find that the occupied $\text{Mn}(e_g)$ band is derived from the z^2-1 orbital, while the unoccupied band is derived from the x^2-y^2 orbital, in a Mn-atom-based *local* coordinate sys-

FIG. 2. Multiplet splitting of the $\text{Mn}(3d)$ orbital for LaMnO_3 as obtained from the density-functional calculation.

tem with the z axis along the long, basal-plane Mn—O bond. This is illustrated in Fig. 3, where we have shown the dominant orbital contribution¹⁴ to the band structure. Occupation of the z^2-1 band gives rise to the $t_{2g}^3 e_g^1$ configuration of the Mn atom for LaMnO_3 . In the mixed compound, the e_g^1 band is progressively depleted with Ca concentration x , with complete depletion for the end-member CaMnO_3 ($x=1$).

Electron bands^{12,16} for LaMnO_3 in the experimentally observed crystal structure are not very different from the band structure shown in Fig. 1(a). Two differences may be noticed: (i) the $\text{O}(2p)$ bands are separated from the $\text{Mn}(3d)$ bands here, a feature that disappears for the experimental structure, and (ii) the e_g^1 and the t_{2g} bands just below the E_f overlap, while for the experimental crystal structure, additional interaction results in a small separation between the e_g^1 and the t_{2g} bands. In spite of this separation, however, the

FIG. 3. Contribution of the $\text{Mn}(3d)z^2-1$ and x^2-y^2 orbitals, to the band structure. The orbitals are with respect to a Mn-atom-based *local* coordinate system with the z axis pointing towards a long Mn—O bond on the basal plane. The width of each band in the figure shown by cross hatching, is proportional to the contribution of the 3d orbital (z^2-1 or x^2-y^2) on a specific Mn atom.

TABLE I. Energy $\bar{\epsilon}_d$ of the central site Mn(3d) level (in Rydberg) for two different values of the "constrained" occupancy n_d for the case of LaMnO₃. The occupancies of the s and p electrons on the Mn site and the total valence charges on the neighboring in-plane (n_{O1}) and out-of-plane (n_{O2}) oxygen atoms are also shown.

n_d	$\bar{\epsilon}_d$	n_s	n_p	n_{O1}	n_{O2}
4.5	-0.44	0.39	0.51	6.05	6.16
5.5	0.33	0.26	0.38	5.96	6.17

excursion of the $z^2 - 1$ character into the t_{2g} group of bands, as seen from the left panel of Fig. 3 near the Γ point, is nevertheless retained in the electron bands for the experimental crystal structure [see inset of Fig. 2(a) in Ref. 16].

To assess the importance of the correlation effects, we have estimated the magnitudes for the on-site Coulomb (U) and the intra-atomic exchange (J) parameters for the Mn atom from constrained density-functional calculations.¹⁵ The Coulomb parameter U was calculated from the dependence of the on-site energy $\bar{\epsilon}_d$ of the Mn(d) orbital on the number occupancy n_d of a central Mn site,

$$\bar{\epsilon}_d = \epsilon_d + U \times (n_d - 1), \quad (1)$$

with the interaction of the central Mn(d) orbitals with the rest of the system switched off. This procedure is somewhat different from the one we reported earlier,¹⁶ where we employed a Slater's transition rule for the calculation of U , but we get very similar results in both cases. By constraining all d electrons on a central Mn site in a 4-atom supercell calculation, we obtain a value of about 10.4 eV for U .¹⁷

In Table I, we show the screening charges on the central Mn atom and the neighboring O atoms, for two different constrained values of n_d . The change in the number of 3d electrons is screened by only about 13% each by the Mn s and p electrons. The four in-plane oxygen atoms together contribute about 36% while the two out-of-plane oxygen atoms contribute a negligible 2% to the screening charge. The rest of the screening charge resides on more distant neighbors. Such relatively poor screening results in the high value for the Coulomb parameter U .

However, since the screening charges reside on the sphere centers in the LMTO calculation, while in reality such charges on neighboring atoms are displaced towards the central atom, the Coulomb interaction may be somewhat overestimated.¹⁸ A lower bound for U is obtained by supposing that the screened charges on the neighboring oxygen atoms are located at the surface of the central Mn sphere, which then yields the maximum value for the error to be about 2.1 eV, with the resultant lower bound of $U \approx 8.3$ eV. Thus, our calculations indicate a value of $U \approx 8-10$ eV, which is consistent with the estimate of $U \approx 7.5$ eV from an analysis of the photoemission data.¹⁹ Such large values for U indicate significant electronic correlation. The calculated magnitude of the on-site parameter is $J \approx 0.86$ eV, which is typical of binary transition-metal oxides, where it varies between 0.78 to 0.98 eV.⁸

With the calculated Coulomb and exchange parameters, we have minimized the LDA+ U functional,⁸ which takes into account the effects of the large Hubbard U term in a meanfield sense. The results discussed in detail elsewhere¹⁶ show that there is a significant spectral redistribution. In particular, while in the LDA calculations, the Mn(3d) bands occur above O(2p) bands, in the LDA+ U calculations in the Mn(3d) bands have shifted down in energy with respect to the O(2p) states and occur in the lower part of a joint band of about 7-eV wide, which is consistent with the valence-band photoemission data.²² Even though the relative positions of the Mn(3d) and the O(2p) bands are reversed in the LDA+ U results as compared to the LDA results, both results are consistent with the 7-eV-wide joint Mn(3d)—O(2p) double-peak structure seen in the valence-band photoemission.²⁰⁻²² A clearer experimental evidence for a large Coulomb U is indicated by the Mn(2p) core-level photoemission spectra, where a satellite peak is seen at the binding energy of ≈ 10 eV.^{19,20,23}

High resolution photoemission measurements have been performed for the ferromagnetic transition of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and for the order-disorder transition of $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$. The band gap collapsed below the Curie temperature and the density of states at the Fermi level increases with cooling. Upon cooling through the order-disorder transition temperatures, T_{CO} , the band gap increases by ~ 50 meV. This change in the gap is consistent with the change in the activation energy above and below T_{CO} estimated from conductivity data. We have also performed soft x-ray magnetic circular dichroism measurements at Mn $L_{2,3}$ edges for ferromagnetic $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$. © 1996 American Institute of Physics. [S0021-8979(96)49308-4]

I. INTRODUCTION

With a discovery of “colossal” magnetoresistance (CMR), mixed-valent manganese perovskites, such as $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$ and $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$, have attracted renewed attention, particularly due to their potential technical application.¹⁻⁵ These manganese perovskites exhibit a variety of electrical and magnetic phases depending on the doping concentration, x , and the temperature, T .⁶ Especially, for a doping range of $\sim 0.2 < x < \sim 0.5$ in which CMR has been observed near the Curie temperature, T_c , the system undergoes a ferromagnetic transition. This magnetic transition is accompanied by a large change in resistance, and further upon heating, the resistivity increases below T_c but decreases above T_c .⁵⁻⁸ Hence, the transition has often been referred to as a paramagnetic insulator to ferromagnetic metal (PI-FM) transition. However, these intriguing resistivity behaviors have been attributed to a spin-dependent scattering mechanism instead of the electronic transition such as the gap closing observed in most metal-insulator transitions.^{7,9}

LaMnO_3 contains Mn^{3+} ($t_{2g}^3 e_g^1; S=2$). Substitution of La sites with alkaline earth elements induces Mn^{4+} ($t_{2g}^3; S=3/2$), and the system becomes mixed valent. The ferromagnetic transition in hole doped LaMnO_3 has been traditionally explained in the framework of the “double-exchange” model, which engenders the spin-dependent scattering mechanism.^{7,10-12} Theoretical calculations based on the model shows that the calculated results qualitatively agree with the observed transport data,⁷ but also reveal significant contrasts such as the insulating behavior above T_c .

Besides the ferromagnetic transition, a real space charge-ordering of Mn^{3+} and Mn^{4+} has recently been reported in a similar family member, $\text{Pr}_{0.5}\text{Sr}_{0.5}\text{MnO}_3$.¹³ Further, in $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$, this charge ordering has been observed in a wide range of doping concentrations, $0.5 < x \leq 0.75$,¹⁴ in which the system has an antiferromagnetic ground state. Upon cooling through the charge-ordering temperature, T_{CO} ,

~ 500 K (40 meV) increase has observed in the resistivity slope, $d[\ln(R)]/d(T^{-1})$, which correspond to the activation energy in a semiconductor model.¹⁴

As a powerful experimental tool to study magnetic structure of ferromagnetic systems and magnetic multilayers, soft x-ray Magnetic Circular Dichroism (MCD) has been introduced.¹⁵⁻¹⁸ Since the manganese perovskites undergo ferromagnetic transition accompanied by the colossal magnetoresistance, MCD measurements on these systems are quite useful to study the magnetic properties.

Here, we present temperature dependent high resolution photoemission data through the ferromagnetic transition temperature, T_c , of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and through the charge-ordering temperature, T_{CO} , of $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$. We also present MCD results on ferromagnetic $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$ at Mn $L_{2,3}$ edges. The organization of the paper is the following. The experimental details are described in Sec. II, and the results and discussions and the conclusions are followed in Secs. III and IV, respectively.

II. SAMPLES AND EXPERIMENTS

The photoemission spectroscopy (PES) and MCD measurements were performed at the AT&T Bell Laboratories Dragon beamline at the National Synchrotron Light Source (NSLS).¹⁹ Polycrystalline $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$ samples were prepared by standard solid-state reaction method. All the samples were oxygen-stoichiometric and x-ray powder diffraction measurements showed single phase patterns. The samples were cleaved in a vacuum better than 1.5×10^{-10} Torr, and during the measurements the temperature was controlled within 1 K. The cleaned surfaces were found to last about 4 hr, as confirmed by absence of 9 eV binding energy peak which is known to appear with surface contamination. All the measurements were repeated at least twice to ensure reproducibility of data and each set of data was obtained from a newly cleaved fresh surface. The high resolution PES spectra were measured at 110 eV photon energy with a 60 meV overall experimental resolution, including the photon and electron kinetic energy

^{a)}Permanent address: Department of Physics, Johns Hopkins University, Baltimore, MD 21218.

FIG. 1. High resolution photoemission spectra of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ ($T_c \approx 260$ K) taken at different temperatures.

resolution. The binding energies were referred to the chemical potential of a clean Pt in electrical and thermal contact with the samples.

For MCD measurements, the photoabsorption spectra were obtained at normal incidence on $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$ by monitoring the sample photocurrent. The samples were scraped in a vacuum better than 1×10^{-9} Torr. A 0.4 Tesla permanent magnet was used for magnetization of samples. Since the Curie temperatures of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$ are 260 and 200 K,⁶ respectively, the spectra were recorded at liquid-nitrogen temperature (~ 80 K). The degree of circular polarization was set $\sim 85\%$, and the photon energy resolution was set 300 meV.

III. RESULTS AND DISCUSSIONS

Figure 1 shows the high resolution PES spectra of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ which has $T_c \approx 260$ K. The wide-scan spectra, which include the valence band and the Ca 3p, O 2s, and La 5p shallow core levels as well, exhibit nearly no difference between $T=80$ K and $T=280$ K, excepting for a minor chemical shift of ~ 70 meV and an intensity variation very near E_F . The magnified near E_F spectra taken at four different temperatures, 80, 150, 240, and 280 K, are shown in the inset. In the 280-K spectrum, no density of states at E_F , $n(E_F)$, is observed indicating the insulating phase. Upon cooling below T_c , $n(E_F)$ gradually increases, and the 80-K spectrum clearly reveals the metallic Fermi edge. These results provide a microscopic evidence for an insulator-metal transition, and the large change in the resistivity as well as the sign change around T_c in the temperature dependence of the resistivity, $d[R(T)]/dT$, can be understood by the insulator-metal transition.

What causes the insulating nature above T_c ? Our photoemission data show negligible $n(E_F)$ above T_c and very tiny $n(E_F)$ even well below T_c , while within the double exchange model, a considerable amount of density of states are expected at E_F both below and above T_c . These contrasts prove that some additional effects to the double exchange model are required to suppress $n(E_F)$ substantially. Recently,

FIG. 2. High resolution photoemission spectra of $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$ taken at 270 K, above the charge ordering temperature, $T_{CO} \approx 250$ K, and at 220 K, below T_{CO} . (a) wide range spectra and (b) spectra near the chemical potential.

the additional effects were also pointed out from a theoretical analysis of the transport data, and a Jahn-Teller polaron effect has been suggested for the candidate.²⁰ However, the Jahn-Teller effect is expected to be at most a few hundred meV, which is an order of magnitude smaller than the conducting e_g bandwidth obtained in the band calculation. Hence, addition to the Jahn-Teller effect, the polaron formation due to a large difference in the ionic size between Mn^{3+} and Mn^{4+} can be an alternative to explain the insulating behavior above T_c as well as the low metallic conductivity below T_c in $\text{La}_{1-x}\text{Ca}_x\text{MnO}_3$.

Figure 2 shows the high resolution PES spectra of $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$ which has been found to exhibit a real-space charge-ordering below $T_{CO} \approx 250$ K,¹⁴ taken at $T=270$ K, above T_{CO} , and at $T=220$ K, below T_{CO} . Except in the region very near E_F , both spectra are exactly identical to each other. The near E_F spectra above and below T_V are compared in Fig. 2(b) and the very near E_F spectra are presented in the inset. Both spectra exhibit no density of states at E_F indicating the insulating phase. Upon cooling through the charge-ordering temperature, T_{CO} , we found that the threshold energy is shifted by ~ 50 meV to higher binding energy. This small increase in the gap is consistent with the observed ~ 40 meV (500 K) increase in the resistivity slope, $d[\ln(R)]/d(T^{-1})$, which corresponds to an activation energy in a semiconductor model. These results show that the breaking of charge ordering is accompanied by ~ 50 meV reduction of the band gap.

Now we present the first MCD spectra of the manganese perovskite system. Mn $L_{2,3}$ edge photoabsorption spectra of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$ by using the magnetic circular dichroism are shown in Fig. 3. I_+ and I_- denote the absorption spectra with the photon helicity direction parallel and antiparallel to the magnetization direction, respectively. The overall shape of the MCD spectrum, $I_+ - I_-$, is quite similar for two different Ca concentrations, while the peak height MCD ratio $(I_+ - I_-)/(I_+ + I_-)$, is found to be slightly

FIG. 3. X-ray Magnetic Circular Dichroism spectra at Mn $L_{2,3}$ photoabsorption edges of ferromagnetic $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$.

larger for the low Ca concentration sample. Taking into account the circular polarizability of 85%, we estimate the L_3 edge MCD ratios' 11% and 13% for $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$, respectively. This result indicates that $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ has slightly smaller magnetization than $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$. Ca doping replaces Mn^{3+} (d^4) with Mn^{4+} (d^3), and the magnetic moment is expected to be reduced with Ca doping. Hence, the smaller MCD effect in the low Ca doped system seems to be consistent with the expected lower magnetic moment. However, it should be noticed that the saturating magnetic field (>4 Tesla) is one order of magnitude larger than the magnetic field used here.⁶ Below the saturating magnetic field, the magnetization strongly depends on temperature and the applied magnetic field. Hence, quantitative analysis should be preceded by detailed studies of the magnetization versus applied magnetic field.

IV. CONCLUSIONS

We have investigated the ferromagnetic transition of $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and the order-disorder transition of $\text{La}_{0.4}\text{Ca}_{0.6}\text{MnO}_3$ using high resolution photoemission spectroscopy. The data show that the insulator-metal transition (the band-gap closing) occurs near the Curie temperature, T_c , and that the band gap increases by ~ 50 meV upon cooling through the charge-ordering temperature T_{CO} . We also present Magnetic Circular Dichroism spectra of ferromagnetic $\text{La}_{0.67}\text{Ca}_{0.33}\text{MnO}_3$ and $\text{La}_{0.8}\text{Ca}_{0.2}\text{MnO}_3$ at Mn $L_{2,3}$ photoabsorption edges.

We have applied extended x-ray absorption fine structure (EXAFS) spectroscopy to study the cation distribution in a series of spin-sprayed NiZn-ferrite films, $\text{Ni}_{0.15}\text{Zn}_y\text{Fe}_{2.85-y}\text{O}_4$ ($y=0.16, 0.23, 0.40, 0.60$). The Ni, Zn, and Fe EXAFS were collected from each sample and analyzed to Fourier transforms. Samples of Ni-ferrite, Zn-ferrite, and magnetite were similarly studied as empirical standards. These standards, together with EXAFS data generated from the theoretical EXAFS FEFF codes, allowed the correlation of features in the Fourier transforms with specific lattice sites in the spinel unit cell. We find that the Ni ions reside mostly on the octahedral (*B*) sites whereas the Zn ions are predominantly on the tetrahedral (*A*) sites. The Fe ions reside on both *A* and *B* sites in a ratio determined by the ratio of Zn/Fe. The addition of Zn displaces a larger fraction of Fe cations onto the *B* sites serving to increase the net magnetization. The fraction of *A* site Ni ions is measured to increase peaking at $\approx 25\%$ for $y=0.6$. At higher Zn concentrations ($y \geq 0.5$) the lattice experiences local distortions around the Zn sites causing a decrease in the superexchange resulting in a decrease in the net magnetization. © 1996 American Institute of Physics. [S0021-8979(96)35808-4]

In spinel oxides, as well as other complex metal-oxide systems, the site and valence distribution of the metallic cations dictate the sample's magnetic and electronic properties. As a result, the need for this type of information has been the subject of much experimental and theoretical research. Traditionally, researchers have empirically studied the effects of substitutional metals on the magnetic and electronic properties of spinel ferrites owing to the difficulties involved with directly measuring the site distribution in these materials. The use of x-ray,¹ neutron diffraction,² and Mössbauer effects (ME)³ have all been used with varying degrees of success. The first two techniques are strongly influenced by the elements' cross section to x rays or neutrons and both are sensitive to the sample mass. ME is an excellent tool for the study of the local environment of Fe ions, being able to extract both structural and magnetic information, but is less effective when dilute or nonmagnetic additives are the focus. In recent years, with the increasing demand for planar ferrite devices the interest in ferrites has shifted to thin films supported by rigid substrates. This has created still more challenges associated with their local structural characterization. In this article we describe the use of extended x-ray absorption fine structure (EXAFS) as a tool to study the site distribution of metal cations in ferrite films. Because this technique offers both element specificity and local structure sensitivity it is ideally suited for such a study. Further, this technique is readily applied to thin films on thick supporting substrates without significant loss of signal-to-noise. Samples studied here are spin-sprayed NiZn-ferrite films [$\text{Ni}_{0.15}\text{Zn}_y\text{Fe}_{2.85-y}\text{O}_4$ ($y=0.16, 0.23, 0.40, 0.60$)] where the Ni concentration is fixed and the Zn concentration is varied at the expense of the Fe.

Samples consist of films prepared using a spin-spray,

ferrite plating process developed by Abe and Tamura.⁴ The films were deposited onto glass substrates with compositions: $\text{Ni}_{0.15}\text{Zn}_y\text{Fe}_{2.85-y}\text{O}_4$ ($y=0.16, 0.23, 0.40, 0.60$). These films were chosen for this particular study because of the three transition metals: one is fixed and the other two are systematically varied, thus simplifying the trends between cation distribution and sample composition. Magnetic measurements were performed using a vibrating sample magnetometer (VSM) and the results were correlated with the structural results obtained from the EXAFS measurements.

Data collection entailed measuring the x-ray absorption coefficient encompassing the *K* edges of Fe (7111 eV), Ni (8333 eV), and Zn (9659 eV) for each sample. Data were collected via a total electron yield (TEY) detection scheme⁶ on beam line X23B⁷ at the National Synchrotron Light Source. Following standard EXAFS analysis procedures⁸ these data were analyzed to obtain Fourier transforms of the EXAFS data. In this form the data directly reflect the average local environment around the absorbing atoms where the peaks in the transform typically represent shells of atoms around the absorber.⁹ Data collected from standards of Fe_2O_3 , Fe_3O_4 , ZnFe_2O_4 , and NiFe_2O_4 were similarly analyzed and compared to theoretical partial radial distribution functions (PRDFs) to assist in identifying the main features of the Fourier transformed EXAFS data. Additionally, theoretical EXAFS data, generated using the multiple-scattering (MS) codes (FEFF 6) of Rehr and co-workers,¹⁰ were used to assist in the identification of Fourier features that arise from multiple scattering events. Together, an interpretation of the data collected from the NiZn-ferrite films was possible.

FIG. 1. The AB₂O₄ unit cell. Heavy lines are used to make clear the fcc packing of oxygen ions ($a_0/2$) and A-site cations (a_0). The B-site cations are distributed on the vertices of four interpenetrating fcc lattices (a_0) whose periodicity is not clearly visible.

The spinel ferrite unit cell has the $fd3m$ space group and is based on a close-packed oxygen lattice where metal cations reside on 8 of the 64 tetrahedral sites (A sites) and 16 of the 32 octahedral sites (B sites). The O ions reside on a face-centered-cubic lattice of $a_0/2$, while the A-site ions reside on the interstices of two interpenetrating fcc lattices of a_0 , and the B-site ions reside on the interstices of four interpenetrating fcc lattices of a_0 . Figure 1 depicts a schematic of a single unit cell illustrating the A- and B-site locations relative to each other and to the O lattice. The close-packed nature of the individual lattices are made clear by the heavily-lined spheres. The A-site cations have 4 O neighbors at a distance of ≈ 1.9 Å, while the B-site cations have 6 O neighbors at a distance of ≈ 2.1 Å.¹¹

Hastings and Corliss⁵ found ZnFe₂O₄ to be a *normal* spinel, meaning that the 8 divalent ions occupy the 8 A sites and the 16 trivalent ions occupy the 16 B sites, and NiFe₂O₄

FIG. 2. Fourier transformed Ni EXAFS data acquired from the Ni_{0.15}Zn_yFe_{2.85-y}O₄ ($y=0.16, 0.23, 0.40, 0.60$) film samples. All transforms were obtained using k^3 weighting and a k range of $2.6-11.7$ Å⁻¹.

FIG. 3. Fourier transformed Zn EXAFS data acquired from the Ni_{0.15}Zn_yFe_{2.85-y}O₄ ($y=0.16, 0.23, 0.40, 0.60$) film samples. All transforms were obtained using k^3 weighting and a k range of $2.6-11.7$ Å⁻¹.

to be an *inverse* spinel, meaning that the 8 divalent ions occupy 8 of the 16 B sites and the 16 trivalent ions randomly occupy the remaining sites. In studies of bulk powders it was found that when Zn is added to the NiFe₂O₄ at the expense of Ni the Zn⁺² ions preferentially occupy the A sites displacing some of the Fe ions to the B sites.¹² We postulate that when Zn⁺² is added at the expense of the Fe ions that a similar redistribution takes place: Zn⁺² preferentially occupy the A sites and displace the Fe ions to the B sites.

Fourier transformed Ni EXAFS data, collected from the Ni_{0.15}Zn_yFe_{2.85-y}O₄ samples, are presented in Fig. 2. These data, and those of Figs. 3 and 4, have been analyzed using identical procedures and parameters and are plotted on the same x and y axes to allow direct comparison with one another. The Fourier peaks seen in Fig. 2 have been identified to correspond with atom pair correlations unique to B sites in the ferrite unit cell.¹³ The chief features which act to fingerprint the B-site are the shell of 6 O⁻² ions near 2.1 Å (appearing at 1.6 Å due to an electron phase shift) and the shell of 6 B-site cations centered near 2.96 Å. The peak centered near 3.2 Å arises predominantly from the 6 A-site cations

FIG. 4. Fourier transformed Fe EXAFS data acquired from the Ni_{0.15}Zn_yFe_{2.85-y}O₄ ($y=0.16, 0.23, 0.40, 0.60$) film samples. All transforms were obtained using k^3 weighting and a k range of $2.6-11.7$ Å⁻¹.

around to the *B* sites, however, this peak is not unique to the *B*-site environment as it also appears with even a larger relative amplitude in the *A*-site environment. The amount of Ni in these samples is fixed at a stoichiometry of 0.15 which corresponds to the filling of 1.2 *B* sites. With decreasing Zn/Fe concentration the Fourier profile remains largely unchanged except for the amplitude of these features. Because the total number of cations remains the same for these samples the change in amplitude cannot arise from a change of coordination. Hence, the changes can only be accounted for by a change in the atomic order (i.e., the Debye-Waller coefficient) of the specific correlations contributing to the Fourier peaks. Fitting of this region of the plot using data generated from the MS FEFF (v6.01) codes indicates that these changes are indeed due to this effect. The trend is one of increasing local order on the *B* site with increasing Zn/Fe concentration.

Figure 3 is a plot of the Fourier transformed Zn EXAFS for the $\text{Ni}_{0.15}\text{Zn}_y\text{Fe}_{2.85-y}\text{O}_4$ samples. The Fourier peaks seen in Fig. 3 have been identified to correspond with atom pair correlations unique to *A* sites in the ferrite unit cell. The chief features which act to fingerprint the *A*-site environment are the shell of 4 O^{2-} ions at 1.9 Å (appearing near 1.5 Å due to a ≈ 0.4 Å electron phase shift) and the shell of 12 *B*-site cations at 3.5 Å (appearing near 3.1 Å due to a ≈ 0.4 Å electron phase shift). The peak centered near 3.1 Å also corresponds with 12 O anions which is also unique to the *A*-site environment. Although the profile of the data changes very little with changes in composition the amplitudes of the Fourier peaks change significantly and in a systematic fashion. The trend is one of increasing amplitude with decreasing Zn/Fe concentration. For the reasons cited above these changes in amplitude are caused by variations in atomic order specific to the *A*-site environment. Hence, the *A*-*B* correlations experience greater disorder for higher Zn/Fe concentration and more order for decreased Zn/Fe concentration. Another noteworthy observation from Fig. 3 is that the Zn-O bond expands with increased Zn concentration. This indicates that for dilute Zn additives the local lattice accommodates these cations without local distortion. However, with increased Zn/Fe concentration the bonds dilate to accommodate the increased Zn content.

Figure 4 is a plot of the Fourier transformed Fe EXAFS collected from the four $\text{Ni}_{0.15}\text{Zn}_y\text{Fe}_{2.85-y}\text{O}_4$ samples. The Fe EXAFS data illustrate features characteristic of both *A*- and *B*-site environments. It is clear, however, that the amplitudes of these Fourier features vary in a systematic manner with sample composition. Upon close inspection, one sees that the variations are largest in the first three peaks of the Fourier transform. The large asymmetric peak centered near 1.5 Å corresponds with the two Fe-O bond distances of the *A*- and *B*-site Fe cations. This peak decreases in amplitude with decreasing Zn/Fe concentration. The large split peak centered near 2.9 Å corresponds with both *A*- and *B*-site environments. The low-*r* split-peak corresponds with the $\text{Fe}_B\text{-M}_B$ correlation, where as the high-*r* split-peak consists of three correlations, specifically, the $\text{Fe}_B\text{-M}_A$, $\text{Fe}_A\text{-M}_B$, and the $\text{Fe}_A\text{-O}$. This peak may also contain amplitude from the $\text{Fe}_A\text{-M}_A$, and two $\text{Fe}_B\text{-O}$ correlations. The low-*r* split-peak

decreases in amplitude with decreasing Zn/Fe concentration while the high-*r* split-peak increases in amplitude for the same compositions. All of these trends can be explained by the site distribution of the Fe cations. From Fig. 3 we know that Zn preferentially occupies the *A* sites for all compositions. This forces a larger fraction of Fe ions to occupy the *B* sites for increased Zn/Fe. Hence, the Fe_B/Fe_A increases with the Zn/Fe causing an increase in the amplitude of the low-*r* peak at 2.6 Å and a decrease in amplitude of the high-*r* peak at 3.1 Å. The oxygen peak, centered near 1.5 Å, varies in amplitude and shape due to the change in occupancy between the six-fold coordination *B* site and the four-fold coordination *A* site. The trends in the Debye-Waller coefficient mentioned in the Ni- and Zn-EXAFS discussion are found from a least squares fitting of the data, using the FEFF generated data, to be small compared to the change in amplitude brought on by the changes in site occupancy.

It was mentioned earlier that Ni-ferrite has an inverted cation distribution and, consequently, its magnetization arises solely from the Ni^{+2} ions. The introduction of Zn^{+2} ions, which prefer the *A* sites, upsets the ferric balance by displacing the Fe cations from the *A* to *B* sites. The effect of a small amount of Zn is to increase the saturation magnetization. This occurs as a result of the Zn^{+2} ions displacing the trivalent Fe ions from the *A* to the *B* sites so that there is no longer a complete cancellation of the Fe moments. The now unbalanced Fe ion moments add to those of the Ni^{+2} ions. We measure magnetization values to increase near linearly with increased Zn concentration for $0 \leq y \leq 0.4$ and then decrease for $y = 0.6$. The decrease in magnetization is due to the deterioration of the superexchange between the *A*-*B* sites brought on by the lattice distortions caused by the increased number of Zn ion on the *A* sites. This local distortion was clearly seen in the Zn EXAFS.

This work was performed at the National Synchrotron Light Source at Brookhaven National Laboratory which is sponsored by the U. S. Department of Energy.

Possible nearly loss-free ferrimagnetic resonance in small samples

J. B. Sokoloff

Northeastern University, Boston, Massachusetts 02115

Relaxation occurs in ferrimagnetic resonance by processes which transfer energy from the uniform precession magnon mode, which is excited in the resonance process, to other magnons and to phonons. The relaxation due to these processes is usually calculated using Fermi Golden Rule time dependent perturbation theory, whose application depends on the modes involved in the relaxation processes forming a continuum. Since for a finite isolated solid this is not generally true, the possibility exists that such relaxation processes might not occur for sufficiently small samples. Because it is reasonable to consider the phonons as belonging to both the sample and sample holder, it is reasonable to assume that they form a continuum. The intrinsic linewidth (i.e., inverse lifetime for a defect-free single crystal), which is due to phonons excited by the Kasuya–Le Craw mechanism, is already comparable to the magnon mode spacing for samples of linear dimensions of the order of $10\ \mu\text{m}$, indicating that finite sample effects could potentially become important for samples of fairly large size. Previous work by the present author on the one-dimensional Heisenberg model has shown that nonlinearity in the magnons can lead to a transition from lossy to loss-free behavior as the sample size decreases, if the temperature is sufficiently low. Here, model calculations of this effect in a two-dimensional Heisenberg model magnet are presented in order to show that loss-free behavior can occur for sufficiently low temperature and sufficiently small sample size. These results open up the interesting possibility of producing high anisotropy magnetic materials as a collection of very small crystals with extremely small linewidths. © 1996 American Institute of Physics. [S0021-8979(96)35908-1]

INTRODUCTION

In a ferrimagnetic resonance (FMR) experiment, an electromagnetic field couples to a magnon mode (usually the zero wave vector or uniform magnon mode). The energy absorbed by this mode from the field is then transferred to other magnon and to phonon modes via various mechanisms,^{1,2} which results in the uniform magnon being given a nonzero linewidth. The mechanism for this can be understood using Fermi's Golden Rule perturbation theory, in which the uniform magnon is scattered into a continuum of other magnons of nearly the same frequency.² When one considers a finite size solid, however, the magnon and phonon modes do not form a continuum, and hence Fermi's Golden Rule will not lead to a nonzero linewidth because, in general, the uniform mode will not be in resonance with any of the excitations of the solid. In previous work, it was suggested that nonlinearity can lead to dissipation in finite solids,³ in the same way that it leads to relaxation to a state of equilibrium in a finite solid, but this only occurs if the mode spacing is smaller than the width of the modes which results from the nonlinearity (because a nonlinear oscillator's resonant frequency depends on the amplitude of the vibrations), because in this case, the system exhibits chaos.^{4,5} There have been other studies that indicate that chaos may be responsible for dissipation and friction in a finite solid which is isolated from its environment.^{5,6} Although it is nearly impossible in most experimental situations to completely isolate a sample from its surroundings, it is possible to make the mode spacing much larger than the width of the nonlinear modes (the spin waves in the present case). Although the phonon modes of the sample alone are discrete, contact between the sample and infinite solid (e.g., the sample holder) will broaden these phonons into a continuum.⁷ In the case of

FMR, however, the energy is first imparted to the uniform magnon mode. Dissipation in this case consists primarily of the transfer of energy from this mode to many of the other magnon modes. Energy can also be transferred directly from the uniform magnon mode to the phonons through the Kasuya–Le Craw (KL) one magnon one phonon mechanism.¹ This mechanism by itself would give a linewidth of less than 1 Oe (about 10^6 Hz) for yttrium iron garnet (YIG).² The magnon mode spacing is already of this order for samples of linear dimensions of the order of $10\ \mu\text{m}$. Although the accepted value among experimentalists for the intrinsic (presumably due to the Kasuya–Le Craw mechanism) FMR linewidth for barium ferrite is 30 Oe,⁸ estimates of the contribution due to the KL mechanism give a value closer to that of YIG.⁹ The remainder of the contribution to the linewidth for macroscopic samples (which is generally much larger than that of the KL mechanism) is due to the transfer of energy to the other magnon modes. From the arguments given above, we conclude that the possibility exists that the contribution to the FMR linewidth from such mechanisms might be eliminated if the sample is sufficiently small (and hence the mode spacing is sufficiently large). The appearance of finite mode width effects on the Suhl instabilities was considered by Schlomann.¹⁰ This work clearly deals with a regime in which the mode spacing is small compared to the width of the nonlinear resonance. In the present case, in contrast, we are interested in much smaller samples for which the mode spacing is much larger than the width caused by the nonlinearity. In support of my claim that small magnetic crystal can exhibit FMR with very small linewidths, I have performed some calculations of the magnetic energy of a small anisotropic classical Heisenberg model magnetic crystal in both a dc and an ac magnetic field. In previous

FIG. 1. (a) The energy (in units of J , the exchange interaction) is shown as a function of the time (in units of \hbar/J) for a 4×4 atom square lattice. (The anisotropy $A=0.3 J$, H multiplied by the Bohr magneton is $0.1 J$, \hbar_0 times the Bohr magneton is $0.01 J$, and $\omega=1.0J/\hbar$.) (Before the dynamics are studied, the system is equilibrated to a temperature of $0.5 J$ using a Monte Carlo calculation.) (b) The results presented in (a) over a larger energy range. (Zero energy occurs in the infinite temperature limit.)

calculations which I reported on such a model, I considered only a one-dimensional model. I showed that there is a well defined transition as a function of system size from a regime in which the system absorbs energy from the ac field (as evidenced by the fact that the energy of the magnet increases as a function of time) to one in which the energy oscillates but does not increase on the average as a function of time.³ The one-dimensional system studied has nondegenerate magnon modes, whereas higher dimensional systems have degeneracy and the minimum mode spacing for samples with the same linear dimensions is much smaller.⁷ It is well known that degeneracy can lead to a situation in which the system becomes chaotic, even for vanishingly small nonlinearity.⁵ This fact opens the question of whether the dissipationless behavior found for the one-dimensional magnet will still occur in higher dimensions. Therefore, in this article, I present calculations on a two-dimensional anisotropic Heisenberg model, which support the occurrence of dissipation in higher than one dimension.

FIG. 2. The energy (in units of J , the exchange interaction) is shown as a function of the time (in units of \hbar/J) for a 10×10 atom square lattice for the same parameters as in Fig. 1.

RESULTS

There are some well established results for the chaotic behavior of classical spins in an ac magnetic field. Frahm and Mikeska¹¹ have found that a single spin with single ion anisotropy in a circularly polarized ac magnetic field, which is in the plane favored by the anisotropy, is a completely integrable problem (i.e., a nonchaotic system), whereas when the field is linearly polarized in the same plane, the system is nonintegrable, exhibiting chaos for sufficiently strong field. Magyari *et al.*¹² have shown that the completely isotropic Heisenberg model with infinite range exchange interaction is integrable. It is also easy to show by simply writing down the equations of motion that for the finite range isotropic Heisenberg model in a uniform ac field, the total spin of the system (i.e., the sum of the spins of all of the lattice sites) satisfies the same equations of motion as for a single spin without anisotropy in a uniform ac field.

The model studied is the classical Heisenberg model with single ion anisotropy, which satisfies the equations of motion

$$\dot{\mathbf{S}}_l = \mathbf{H}_{\text{eff}} \times \mathbf{S}_l, \quad (1)$$

where $\mathbf{H}_{\text{eff}}^\alpha = -\partial H / \partial S_l^\alpha + h(t) \delta_{\alpha,x}$, where $H = -\sum_{j,l} J_{j,l} \mathbf{S}_j \cdot \mathbf{S}_l - A \sum_j (S_j^z)^2 - H_0 \sum_j S_j^z$, $h(t) = h_0 \cos(\omega t)$ is the applied ac field, H_0 is the dc field, and A is the anisotropy. These equations were solved using a Runge-Kutta integration routine, and the total energy of the system was calculated as a function of time. Energy was conserved in these calculations to at least fourth place accuracy. Results for a two-dimensional lattice with free end boundary conditions with a side length of four atomic distances is shown in Fig. 1. Results for a side length of ten atoms, with the same parameters as in Fig. 1, are shown in Fig. 2. As can be seen, there is clearly a transition from nonidissipative to dissipative behavior as a function of system length, in the sense that for the smaller size system there is clearly no absorption of energy, whereas for the larger system, the energy clearly increases as a function of time. Thus, mode degeneracy, which certainly occurs in

higher than one dimension, does not appear to prevent the occurrence of a transition from a dissipationless state.

QUANTUM MECHANICAL EFFECT

In this article, it has been assumed that classical dynamics was a good description of the magnetic system. Since classical mechanics is only an approximation to the correct quantum mechanical treatment, which is based on the Schrödinger equation, which is linear, it is important to question whether the present mechanism for dissipation will work in a quantum mechanical treatment. This question has been considered for other models, which can be solved both classically and quantum mechanically, and which exhibit chaos in the classical limit.¹³ It was determined in these studies that the system initially behaves classically (and hence is able to exhibit chaos) for a time of the order of $\lambda^{-1} \ln(I/\hbar)$, where λ is a typical Lyapunov exponent and I is a typical action for the problem. For longer times, quantum mechanics takes over and classical chaos is no longer possible. For this problem, we expect I to be of the order of J times a typical time in the problem such as the inverse of a typical magnon frequency, which is of the order of \hbar/J , and hence, the critical time for classical dynamics to no longer be valid is of the order of the inverse Lyapunov exponent. Thus, unless the inverse Lyapunov exponent is ridiculously long, in which case effects dependent on the occurrence of classical chaos would be almost undetectable, long time steady state dissipation cannot occur in an isolated system. The fact that interaction with the environment generally seems to suppress the occurrence of quantum phenomena¹⁴ could justify the use of the classical Heisenberg model to treat the problem of dissipation in a magnetic system. This is still a controversial

point,¹⁵ however. The question of the existence of dissipation in a small isolated magnetic system, raised in this article, could possibly provide a good testing ground for answering these questions experimentally.

Anomalous low dimensional system: Study of magnetism and electrical conductivity in $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$

G. Cao, S. McCall, F. Freibert, M. Shepard, P. Henning, and J. E. Crow

National High Magnetic Field Laboratory, Florida State University, Tallahassee, Florida 32306-4005

The magnetic susceptibility $\chi_{\parallel}(H\parallel b)$, $\chi_{\perp}(H\perp b)$ ($2\leq T\leq 700$ K) and electrical resistivity $\rho(T)$ ($2\leq T\leq 300$ K) of single crystal $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ ($\delta\geq 0$) with various oxygen content were measured. The crystal structure of this compound is monoclinic with single, double, and triple chains along the b axis. The most striking feature of this compound is the drastically large anisotropy reflected in the resistivity which exhibits metallic behavior along chains and semiconducting behavior perpendicular to the chains. The resistivity ratio for these two directions ($\rho_{\perp}/\rho_{\parallel}$) is larger than 10^5 . This ratio is exceptionally large, indicating that the anisotropy of the bandwidth is substantial. It is remarkable that, after reduction of oxygen content in the system, the magnetic susceptibility undergoes a drastic change, whereas the electrical resistivity along the conducting chains is altered only slightly. It is argued that the different sensitivity to oxygen content reflected in magnetic and transport properties may be attributed to the complexity of the crystal structure. The striking observations presented here may suggest a one-dimensional system that possesses unique physical properties. © 1996 American Institute of Physics. [S0021-8979(96)36008-6]

INTRODUCTION

The discovery of superconductivity in the cuprates has led to a resurgence of interest in the $3d$ transition-metal oxides. However, physical properties of the $4d$ and $5d$ metal oxides, though recently drawing moderate attention, remain largely unexplored. One class of these oxides is the ruthenium oxides which exhibit a rich variety of unusual magnetic behavior while also possessing rather high electrical conductivity. While exploring magnetic and electrical properties, looking, in part, for superconductivity in the oxides, we have found that $\text{Na}_2\text{Ru}_4\text{O}_9$ displays an anomalously large anisotropy in conductivity with metallic behavior in one direction and semiconducting behavior in others. In addition, the magnetic susceptibility parallel to the chains χ_{\parallel} has a maximum in the vicinity of 70 K with significant anisotropy in χ_{\parallel} and χ_{\perp} below the maximum. It is remarkable that, after reduction of oxygen content in the system, the maximum completely disappears, and $\chi(T)$ is radically changed, whereas the electrical resistivity along the b axis is altered only slightly.

EXPERIMENTAL

The crystal structure of $\text{Na}_2\text{Ru}_4\text{O}_9$ shown in Fig. 1¹ is monoclinic with $a=23.180$, $b=2.832$, $c=10.990$ Å, $\beta=104.50^\circ$, and space group $C2/m$.^{1,2} The Ru_4O_9 network is formed by single, double, and triple chains of RuO_6 octahedra sharing edges. These chains share oxygen on the corner of the RuO_6 octahedra and run parallel to the shortest axis (b axis). The sodium ions are inserted in three different sites in the tunnels.¹ This compound is very stable in air. Additionally, the results of x-ray powder diffraction indicate that $\text{Na}_2\text{Ru}_4\text{O}_9$ can accommodate a relatively large oxygen deficiency without a breakdown of its crystal structure, however, the monoclinic structure appears to be unstable with small oxygen overdropping.

The starting materials were Na_2CO_3 and RuO_2 with purity of 99.9%. The single crystals of $\text{Na}_2\text{Ru}_4\text{O}_9$ were then grown out of a Na-rich flux, yielding needle-shaped crystals

with the largest dimension along the b axis. The size of the average crystals is of $1.0\times 10\times 0.5$ mm³. Deoxygenated $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ ($\delta>0$) crystals were obtained by sealing as-grown crystals in evacuated quartz tubes which were then heated at 400–550 °C for 100 h. The crystal structure and lattice parameters obtained from powder x-ray diffraction patterns of both as-grown and deoxygenated single crystals were in excellent agreement with published data.² Scanning electron microscopy (SEM) and energy dispersive x-ray (EDX) were also performed on the single crystals, confirming that the crystals were of high quality. The electrical resistivity was measured using four standard probe techniques, and the magnetic susceptibility was measured using a superconducting quantum interference device (SQUID) magnetometer.

RESULTS AND DISCUSSION

Shown in Fig. 2 is the magnetic susceptibility $\chi_{\parallel}(H\parallel b)$ and $\chi_{\perp}(H\perp b)$ vs temperature for an as-grown crystal $\text{Na}_2\text{Ru}_4\text{O}_9$. A broad maximum occurs at 70 K. The orientation dependence of χ below the maximum seems to be attributed to the anisotropy of sublattice magnetization and would suggest an antiferromagnet. However, no anomaly in the vicinity of 70 K in specific heat is seen, implying that the maximum observed may not be associated with long range order. The low temperature Curie tail is somehow sample dependent, and probably an extrinsic effect. The magnetic susceptibility $\chi(T)$ well above the peak ($100\text{ K}<T<300\text{ K}$) indicates an extremely narrow electronic band and can be described by a modified Curie-Weiss law, i.e., $\chi=\chi_0+C/(T+\theta)$, where χ_0 is a temperature independent contribution to $\chi(T)$, C is the Curie constant, and θ is the Curie-Weiss temperature. Fitting $\chi(T)$ for $100\leq T\leq 300$ K to the Curie-Weiss law leads to the values of $\chi_0=7.92\times 10^{-4}$ and 1.06×10^{-3} emu/mol for χ_{\parallel} and χ_{\perp} , respectively. These values are unusually large when compared to those typically reported for ordinary metals (10^{-5} emu/mol). Such large values of χ_0 , when taken as a measure of

FIG. 1. Crystal structure of $\text{Na}_2\text{Ru}_4\text{O}_9$ (Ref. 1). Note: The b axis, i.e., the multichain direction, is perpendicular to the paper.

the density of states at the Fermi level, represent either a highly correlated spin state or strong electron-electron correlation.

The valence state of Ru for $\text{Na}_2\text{Ru}_4\text{O}_9$ is Ru^{4+} ($4d^4$) which is in the low-spin state with $S=1$. Were the charges localized, the material would be an insulator. $\text{Na}_2\text{Ru}_4\text{O}_9$ is a metallic conductor along the b axis which will be described later, and remains metallic below the maximum. The effective magnetic moment obtained from χ is $1.67 \mu_B$ for both χ_{\parallel} and χ_{\perp} , which is only 58% of the Hund's rule value ($2.83 \mu_B$), assuming quenching of orbital contribution.

The resistivity $\rho_{\parallel}(T)$ for the as-grown $\text{Na}_2\text{Ru}_4\text{O}_9$ single crystal measured with electrical current running along the b axis is shown in Fig. 3. While showing metallic behavior, $\rho_{\parallel}(T)$ decreases with a slightly negative curvature from 0.54 to 0.24 m Ω cm as temperature decreases from 300 to 40 K. No unusual structure is apparent in $\rho_{\parallel}(T)$ in the vicinity of

FIG. 2. The magnetic susceptibility $\chi(T)$ vs temperature for the as-grown single crystal $\text{Na}_2\text{Ru}_4\text{O}_9$.

the maximum observed in $\chi(T)$. Near 40 K, however, a slightly sharper drop is developed. For $T < 30$ K, $\rho(T)$ is well described by $\rho(T) = A + BT^2$. The resistivity characterized by the T^2 dependence is reflective of spin fluctuations which apparently dominate the scattering process in this temperature region.

The most striking feature of the conductivity in this compound, however, is the drastically large anisotropy reflected in the resistivity. Also shown in Fig. 3 is the resistivity perpendicular to the b axis, i.e., the chain direction. Yet, like $\rho_{\parallel}(T)$, in the vicinity of 40 K, $\rho_{\perp}(T)$ displays a slight but well defined slope change which, again, may be associated with the reduction of spin scattering. The most noteworthy feature is the extremely large anisotropy, i.e., the ratio of $\rho_{\perp}(T)/\rho_{\parallel}(T)$ at $T=280$ and 2 K is about 2×10^5 and 7×10^5 , respectively. Evidently, the resistivity with such a severe anisotropy suggests that the nature of electron scattering processes governing the conductivity in these two directions must be completely different. Although the anisotropy in conductivity is commonly seen in many compounds and alloys such as high T_c materials, the ratio of the resistivity for the conducting direction and the less conducting direc-

FIG. 4. The magnetic susceptibility $\chi(T)$ vs temperature for the deoxygenated single crystal $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ ($\delta > 0$).

tion is typically much smaller, e.g., $\rho_c/\rho_{ab}=20\text{--}100$ for $\text{YBa}_2\text{Cu}_3\text{O}_7$.

The unusual behavior of $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ becomes even more interesting after comparing magnetic and transport properties observed in crystals which were deoxygenated. Shown in Fig. 4 is magnetic susceptibility $\chi_{||}$ for $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ with $\delta > 0$ vs temperature for $2 \leq T \leq 700$ K. The great fascination of this data is that the system undergoes a drastic change in magnetic spin interactions due to reduction of oxygen content. The low temperature up-turn in $\chi_{||}$ may reflect a small impurity phase. However, the unusual temperature dependence at higher temperatures is quite interesting. For $60 \leq T \leq 270$ K, $\chi(T)$ is essentially independent of temperature, and then develops a rapid up-turn near 270 K which is followed by a saturation occurring in the vicinity of $T=600$ K. The origin of such behavior is not yet clear. However, it cannot be ruled out that oxygen deficient $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ ($\delta > 0$) may be involved in one-dimensional spin interactions which leads to an energy gap opening below 270 K. In fact, the behavior displayed by $\chi(T)$ mimics those of known low dimensional systems, such as Y_2BaNiO_5 ,³ CuGeO_3 ,⁴ SrCu_2O_3 ,⁵ etc.

On the other hand, the electrical resistivity $\rho(T)$ for the deoxygenated sample changes only slightly with an increase in linearity down to 40 K and a mild decrease in magnitude. Yet, above 40 K, $\rho(T)$ shows, to the first order approximation, the linear- T behavior with the slope $d\rho/dT=1.16 \times 10^{-6}$ ($\Omega \text{ cm K}^{-1}$). Interestingly, this linear- T behavior, though with the faster slope ($10^{-7} \Omega \text{ cm K}^{-1}$ for

$\text{YBa}_2\text{Cu}_3\text{O}_7$, for instance), is reminiscent to that observed in optimally doped high T_c superconductors when $T > T_c$. The linear- T dependence in $\rho(T)$ is thought to be non-Fermi liquid behavior. Below 30 K, the temperature dependence of $\rho(T)$ evolves the T^2 behavior, which is also seen in the as-grown sample. Fitting $\rho(T)$ to $A+BT^2$ for $0 < T < 30$ K yields $A=2.2 \times 10^{-4}$, 2.0×10^{-4} ($\Omega \text{ cm}$) and $B=3.2 \times 10^{-8}$, 2.0×10^{-8} ($\Omega \text{ cm K}^{-2}$) for the as-grown and deoxygenated samples, respectively. While A , which is due to the impurity scattering, remains essentially unchanged, B for the deoxygenated sample is almost 40% smaller than that for the as-grown sample. However, the change in the conductivity is by no means significant when compared to that in magnetism.

Nevertheless, it becomes clear that $\text{Na}_2\text{Ru}_4\text{O}_{9-\delta}$ ($\delta \geq 0$) is indeed unique in that it shows a wide range of unusual properties that may be attributed to one-dimensional behavior. The most striking feature of this compound is the drastically large anisotropy reflected in resistivity which exhibits metallic behavior along one direction and semiconducting behavior along others. The resistivity ratio for these two directions $\rho_{\perp}/\rho_{||}$ is larger than 10^5 . This result doubtlessly suggests that the bandwidth in this material is highly anisotropic. Consistently, the magnetic susceptibility also suggests occurrence of low dimensional behavior with a maximum in the vicinity of 70 K. It is remarkable that, after reduction of oxygen content in the system, the magnetic susceptibility undergoes a drastic change in spin interactions, whereas the electrical resistivity along the b axis alters only slightly with an increase in linearity. The striking observations reported here require more careful study including measurements of the oxygen deficiency in the deoxygenated samples. These and other studies are being pursued.

Growth of epitaxial films of iron oxide, nickel oxide, cobalt oxide, strontium hexagonal ferrite, and yttrium iron garnet by laser ablation (abstract)

Robin J. Kennedy

Physics Department, Florida A&M University, Tallahassee, Florida 32307

Thin films of iron oxide, nickel oxide, cobalt oxide, strontium hexagonal ferrite, and yttrium iron garnet have been grown by laser ablation. With the exception of Co_3O_4 deposited on LaAlO_3 , the first three materials deposited on $[100]\text{LaAlO}_3$, SrTiO_3 , and MgO result in high quality c axis $[100]$ growth. Co_3O_4 deposited on LaAlO_3 produces highly oriented but random in-plane growth. Similar highly oriented but random in-plane growth occurs for all three materials deposited on glass. The same three materials deposited on cubic zirconia grow $[111]$ oriented and twinned. Strontium hexagonal ferrite and yttrium iron garnet have been deposited on $[111]$ large lattice constant garnet. Epitaxial $[0001]$ films are obtained for the former while the latter gives $[111]$ -oriented films. For yttrium iron garnet the closeness of lattice match to the substrate necessitates that the mosaicity (rocking curves) obtained from area maps be compared to the growth temperatures and pressures to determine the optimum growth conditions for epitaxiality. © 1996 American Institute of Physics. Resolution of conflicts concerning Fe_{16}N_2 (abstract)

A. S. Arrott

Simon Fraser University, Burnaby, British Columbia, V5A 1S6, Canada

The 1994 3M-Intermag meeting featured an invited session on Fe_{16}N_2 in which many of the research workers in this exciting field put forth apparently conflicting views on the nature and possibilities for the use of, perhaps, the most promising transition metal based alloy for magnetic applications. The debate centers on the promise of $3\mu_B$ per atom at transition metal densities if pure Fe_{16}N_2 could be made. A particularly compelling resolution of the conflicts was not mentioned at the meeting, even though it has been in the past. The conflict arises primarily from the original classification of Fe_{16}N_2 as a phase denoted by α'' to distinguish it from Fe_8N classified as a phase denoted by α' and the substitutional alloy $\alpha\text{-Fe(N)}$. The conflicts arise because data are interpreted as a mixture of two phases α' and α'' . For any measured property, it is then sufficient to know the ratio of the two component phases for two different compositions to deduce the apparent properties of the individual phases. But this is not the case. The distinction between α'' and α' is not that of two separate phases but, rather, the end points of a continuum characterized by the degree of order. This makes it necessary to produce the fully ordered state in order to determine its properties, unless it is possible to have enough data about those properties for various degrees of order to justify extrapolation to the fully ordered state. The most ordered Fe_{16}N_2 is produced using molecular beam epitaxy. It also shows the highest magnetic moments. The high magnetic moments are supported by Mössbauer measurements of large hyperfine fields in bulk materials (not the molecular beam epitaxy material) and by some of the theoretical calculations for the ordered state. One of the criticisms of the molecular beam epitaxy work is that those thin films do not decompose into Fe_4N and Fe(N) on heating as do bulk alloys of the same composition. (The implication is that the thin films contain something else.) But this criticism is not valid, simply because one cannot predict the stability of a highly ordered state from observations of a weakly ordered state. This is particularly the case where the ordering is accompanied by large lattice distortions. The existing literature is analyzed to extract the dependence of magnetic moment on the degree of order. These considerations lend support to those who are pursuing Fe_{16}N_2 for its potential for producing a magnetic material with $3\mu_B$ per atom at transition metal densities. How to increase the degree of order in bulk materials becomes a central concern. © 1996 American Institute of Physics. [S0021-8979(96)81608-3]

Influence of the plastic anisotropy on the magnetic properties of a nonoriented 3% silicon iron

E. Hug, O. Hubert, and M. Clavel

LG2mS, URA CNRS 1505, Université de Technologie de Compiègne, BP649, 60206 Compiègne, France

Modifications of the magnetic properties of a nonoriented 3% SiFe alloy with plastic strains are reported. The samples have been tested along rolling and transverse directions lying in the sheet plane by means of a suitable experimental system of measurements using a 50 Hz sinusoidal magnetic field. The magnetic properties markedly deteriorate when measurements are carried out in the direction of the applied stress. This phenomenon is less important perpendicular to the applied stress. Quasistatic experiments ($f=0.1$ Hz) have been accomplished to separate the total losses into hysteresis and dynamic components. Hysteresis losses strongly increase and dynamic losses sensitively decrease with the plastic deformation whatever the direction in sheet plane. Compression-tension fatigue tests carried out have shown that the material displays a strong kinematic strengthening behavior representative of internal and long range stresses in the strained sample. The degradation of the magnetic properties of nonoriented 3% SiFe alloys with plastic strains is the result of two effects: one due to dislocations and another due to internal stresses. The latter display along the direction of magnetic measurements the same effects as an outside elastic stress. © 1996 American Institute of Physics. [S0021-8979(96)36108-2]

I. INTRODUCTION

Plastic strains are induced in a rotating electrical machine lamination during its manufacture and can damage its magnetic properties. These deformations result in the generation of dislocations which cause the magnetic properties of electrical steel sheets to deteriorate,¹ especially in the range of low strains level, say, 0%–5%, and for low and medium magnetic field amplitudes (0–5000 A/m).^{2,3} These experimental results have been obtained for mechanical stresses and magnetic measurements in the same direction. Nonoriented (N.O.) alloys are generally considered to be magnetically isotropic. The question arises whether the magnetic properties remain isotropic after cold drawing.

In the present article we are dealing with the magnetic properties of a N.O. 3% SiFe along the rolling (RD) and the transverse (TD) directions. The influence of a constant plastic strain imposed along one of these two directions is studied. In addition, tension-compression fatigue tests have been performed with a view to identify the internal stresses in the sample after strengthening. The influence of these stresses on the magnetic properties of N.O. SiFe alloys is discussed.

II. PROCEDURE

Magnetic measurements have been performed on N.O. 3% SiFe alloys (0.5 mm thick). Samples (20×20 mm) have been cut from the unstrained laminations and from the middle of the tensile test specimens previously strained at plastic deformation level $\epsilon_p=4.5\%$ [$\epsilon_p=(L-L_0)/L_0$ where L_0 is the initial length and L is the final length of the specimens]. Tensile tests have been carried out at room temperature and constant strain rate.

Magnetic characteristics have been investigated along RD and TD by means of a suitable experimental system of measurements described elsewhere.^{2,4} A quasistatic excitation ($f=0.1$ Hz) and a 50 Hz sinusoidal magnetic field have

been used. A number of numerical calculations and calibrations were made to confirm the accuracy of this experimental apparatus.

Tension-compression fatigue tests ($\Delta\epsilon_p/2=0.25\%-1\%$) have been carried out on thicker hot rolled 3% SiFe specimens (3 mm). Appropriate heat treatment ensures the same properties (magnetic, mechanical, and metallurgical) between these samples and the final manufactured product.

III. EXPERIMENTAL RESULTS

A. Magnetization characteristics and core losses

The initial magnetization curves (maximum magnetic flux density B_m vs maximum magnetic field H_m) measured along RD and TD are plotted in Figs. 1 and 2 for $f=50$ Hz. A weak anisotropy of the initial magnetic properties (unstrained specimens) is observed. In order to study the plastic anisotropy of the magnetic properties of the material, 4.5% of plastic strain is applied along RD or TD. The magnetic measurements are then implemented along either the tensile or cross directions. The evolution of the magnetization curves is shown in Figs. 1 and 2. The outcome of the experiments shows that the magnetic properties markedly deteriorate when measurements are carried out in the direction of the applied stress. Crossing experiments, i.e., tensile test in RD or TD and magnetic test at 90°, indicate an attenuated effect of the plastic strain on the magnetic properties. Clearly, the decay of the magnetic properties along RD is more important with an applied stress lying along RD than along TD. The magnetic properties along TD behaves similarly: the decay is more sensitive with the applied stress parallel to TD than parallel to RD. This effect is slightly less for magnetic measurements along the transverse direction.

Quasistatic experiments ($f=0.1$ Hz) carried out on both undeformed and deformed samples allow us to determine the various hysteresis parameters, namely, hysteresis losses W_h [J/(kg cycle)] and coercive field strength H_c . Using the hy-

FIG. 1. Magnetization curves of a N.O. 3% SiFe alloy measured along the rolling direction, $f=50$ Hz. Influence of a plastic strain applied along either the rolling or the transverse directions.

pothesis of the separation of losses,⁵ the dynamic losses W_d for $f=50$ Hz are extracted from $W_d = W_t - W_h$, with W_t the total losses per cycle. In Table I the different values of W_t , W_h , and W_d are tabulated for the plastic strain along the rolling direction. As is made clear by this table, W_h strongly increases and W_d decreases with the plastic strain. On the whole, there results an increase of the total energy losses. Coercive field strength measurements give for the unstrained samples $H_c=43$ A/m along RD and $H_c=79$ A/m along TD. H_c reaches 162 A/m along RD and 152 A/m along TD after straining along RD. Energy losses and coercive field strength behave similarly when the plastic deformation is applied along the transverse direction.

(W_t : total losses; W_h : hysteresis losses; W_d : dynamic losses; RD: rolling direction; TD: transverse direction; $W_{0.8}$, $W_{1.4}$: energy losses for $B_m=0.8$ and 1.4 T).

$W = P/f$ (J/kg cycle)	RD, $\epsilon_p=0\%$	RD, $\epsilon_p=4.5\%$	TD, $\epsilon_p=0\%$	TD, $\epsilon_p=4.5\%$
$W_{h0.8}$	0.0099	0.0495	0.0158	0.0495
$W_{d0.8}$	0.0043	0.0035	0.0052	0.0025
$W_{t0.8}$	0.0142	0.0530	0.0210	0.0520
$W_{h1.4}$	0.0342	0.1090	0.0560	0.1300
$W_{d1.4}$	0.0552	0.0050	0.0440	0.0200
$W_{t1.4}$	0.0894	0.1140	0.1000	0.1500

B. Mechanical behavior of the alloy and internal stresses

The study of internal stresses which may exist inside the sample after strengthening requires plastic fatigue experiments. The total applied stress σ may be conveniently expressed as follows (Fig. 3): $\sigma = \sigma_e + R + X$. σ_e is the initial yield stress, R the isotropic, and X the kinematic components of the strengthening.⁶ R and X are obtained from fatigue test results and applied to a monotonous tensile test (Fig. 4). The results highlight a strong kinematic strengthening behavior of the material representative of strong internal and long range stresses in the deformed sample.

IV. DISCUSSION

The degradation of the magnetic properties of N.O. 3% SiFe alloys with plastic strains seems clearly to result from two effects: a first one representative of the metallurgical defects created by strengthening and a second one due to the internal stresses present in the sample after straining.

It has been shown in a previous article³ that small dislocation tangles are created during cold drawing in the range 0%–5% of plastic strain. These defects act as pinning centers for the magnetic domain walls.⁷ As a result, H_c and W_h rise dramatically with small increases in plastic strains. Indeed, these two parameters are representative of the irreversible changes of magnetization due to pinning/unpinning of the magnetic domain walls against dislocation tangles. In view of our results, the growth of H_c and W_h can be considered to

FIG. 3. Determination of the isotropic (R) and the kinematic (X) components of the strengthening from plastic test experiments.

FIG. 4. Variation of the isotropic (R) and the kinematic (X) components of the strengthening with the monotonous plastic strain (tensile test experiments).

be independent of the direction of straining. The initial magnetic anisotropy of the alloy is roughly maintained. The dynamic losses, on the other hand, are representative of the eddy current losses due to changes in magnetic flux in the metallic samples. The dislocation tangles result in many more pinned magnetic walls. The motion of each wall is then reduced. Consequently, the changes in magnetic flux produce less eddy current losses in the deformed specimens because dislocation tangles lead to more walls moving smaller distances.

Beside the isotropic effect of dislocation tangles, it is necessary to take into account the internal stresses in the samples. The latter give rise to a plastic anisotropy. After a tensile test, there is zero exterior applied stress. Considering an area perpendicular to the tensile direction, the sum of stresses on this area is on average zero. Nevertheless, the plastic anisotropy (seen as the strong kinematic behavior in Fig. 4) can be explained by the existence of compressed areas alternating with tensile ones. Moreover, the dislocation network presents many inhomogeneities (tangles, grain boundaries,...). Following Mughrabi,⁸ this configuration implies that strong tension areas (volume V_t) are enclosed in the dislocation tangles and grain boundaries. The latter are counterbalanced by much larger areas of weakly compression stresses (volume V_c). V_c is then larger than V_t in the

tensile direction and the magnetic properties along this direction are on average dominated by compression effects. Consequently, an internal tension stress effect does exist perpendicular to the tension test direction (Poisson's effect).

This could explain the increase of the degradation of the magnetic properties when magnetic tests are carried out along the tensile test direction. Conversely, degradation of the magnetic properties with the plastic deformation are less sensitive when magnetic tests are carried out perpendicular to the tensile test direction. The residual stresses which exist in direction of the measurements display the same effect as an outside elastic stress.⁹ This phenomenon is less sensitive for magnetic measurements along TD. This could be related to the small initial anisotropy of the mechanical properties of the material.

V. CONCLUSION

The investigation of the magnetic properties of a N.O. 3% SiFe with plastic strain, frequency, and orientation lying into the sheet plane allows the following conclusions.

- (1) The strong degradation of the magnetic properties of a 4.5% plastic strained alloy (increase of W_h and H_c) is the consequence of the strong pinning effect of the dislocation tangles on magnetic domain walls.
- (2) The dynamic losses decrease with plastic strains. The changes in magnetic flux produce less eddy current losses in the strained samples because dislocation tangles lead to more magnetic domain walls moving smaller distances.
- (3) The strengthening of the material gives rise to an important plastic anisotropy because of the presence of strong internal stresses after the tensile test. This tends to increase the magnetic degradation when magnetic tests are carried out along the tensile test direction and conversely to reduce this degradation when magnetic tests are made perpendicular to it.

S. Hashi, K. Ishiyama, and K. I. Arai

Institute of Electrical Information, Tohoku University, Sendai, 980-77, Japan

It has been actually required in recent years to decrease iron losses in transformer cores, as increment of electric energy consumption in all industries and homes. Answering to such requirements, Arai *et al.* developed a new type magnetic core material; it was tertiary recrystallized Si steel with 50 μm thickness, and it was of as low iron loss as an amorphous materials one.¹ The Si steel was made by an annealing in a vacuum of 1×10^{-3} Pa and at a temperature of 1200 °C. In this study, we prepared samples for measurements from (110)[001] grain-oriented 3%Si steel with 300 μm thickness. We coldrolled them to about 50 μm using a four-high rolling mill, and then annealed in an atmosphere of highly pure Ar gas, from a point of view of saving energy. We investigated effects of annealing time, heating rate and gas flow rate on magnetic properties. The annealing temperature was fixed at 1000 °C. Hysteresis loops were drawn with single-sheet tester. Grain structure and its direction were decided by etch pit method. Coercive force H_c and induction B_8 which is the induction at 800 A/m applied field were obtained from the hysteresis loops. The magnetic properties were somewhat changed according to the annealing condition. The coercive force varied from 5 to 30 A/m, and the induction varied from 1.45 to 1.85 T. The best properties, H_c was 5 A/m and B_8 was 1.85 T, were obtained under the annealing condition; annealing time was 60 min, heating rate was 3 °C/s, and gas flow rate was 2 $\mu\text{L}/\text{min}$. The surfaces of the samples were not covered with tertiary recrystalline, but wholly with secondary recrystalline. About 90% grains were (110) plane, the rest was (100) plane. And about 90% [001] axes oriented to the rolling direction within five degree misorientation. © 1996 American Institute of Physics.

Magnetic power losses have been experimentally investigated and theoretically predicted over a range of frequencies (direct current—1.5 kHz) and peak inductions (0.5–1.5 T) in 1-mm-thick FeSi 2 wt. % laminations. The direct current hysteresis properties of the system are described by the Preisach model, with the Preisach distribution function reconstructed from the measurement of the recoil magnetization curve ($B_p = 1.7$ T). On this basis, the time behavior of the magnetic induction vs frequency at different lamination depths is calculated by a finite element method numerical solution of Maxwell equations, which takes explicitly into account the Preisach model hysteretic $B(H)$ relationship. The computed loop shapes are, in general, in good agreement with the measured ones. The power loss dependence on frequency is predicted and experimentally found to change from a $\sim f^{3/2}$ to a $\sim f^2$ law with increasing peak induction. © 1996 American Institute of Physics. [S0021-8979(96)36208-9]

I. INTRODUCTION

Power loss phenomena in soft magnetic laminations can be understood and assessed to a good extent through the statistical description of domain wall dynamics and the related development of new concepts in the Preisach modeling of hysteresis.¹ Several interesting problems arise when this interpretative framework is applied to bulk materials and the related skin effects.² In fact, one has to properly characterize the hysteretic magnetic behavior of the sheet, solve Maxwell equations in the presence of hysteresis, and carry out convenient dynamic hysteresis measurements in order to appropriately test the model predictions.

In this article, we study the dynamic behavior of 1-mm-thick FeSi sheets, for frequencies from direct current (dc) to 1.5 kHz and peak inductions in the interval from 0.5 to 1.5 T. The material hysteresis properties are described by the Preisach model (PM), and Maxwell equations are solved by the finite element method (FEM), and by using the fixed point (FP) technique to treat the nonlinear hysteretic behavior of the material. This requires the use of PM in a reversed fashion, in order to obtain, at each iteration step, the time behavior of the local field \mathbf{H} from the known local induction wave form.³ From the knowledge of the magnetic flux density distribution, the dynamic hysteresis loops and the local losses at different frequencies can be calculated.

We have found that the calculated loop shapes are in general in good agreement with the measured ones. At low peak inductions B_p , the skin effect prevents the complete flux penetration in the sheet and the power loss dependence on frequency is close to a $f^{3/2}$ law. With increasing B_p , however, the skin effect is no longer able to hinder the flux penetration and a complicated phase shift pattern in the flux densities at different lamination depths sets in. In this case the power loss vs frequency law moves to a f^2 law.

The present approach does not take into account magnetic domain effects responsible for excess losses. This as-

pect could be dealt with by using the dynamic Preisach model instead of the conventional one.^{1,4}

II. THEORETICAL MODELING

Calculations were based on the standard FEM solution of Maxwell equations expressed in term of the vector potential \mathbf{A} . The starting point is the equation

$$\nabla \times [H(\nabla \times \mathbf{A})] = -\sigma \frac{\partial \mathbf{A}}{\partial t} + \frac{\sigma}{S} \int_{\Omega} \frac{\partial \mathbf{A}}{\partial t} dS', \quad (1)$$

together with nonhomogeneous Dirichlet conditions, which impose the stated flux wave form. In Eq. (1), σ is the electric conductivity and Ω is the cross section of the lamination with area S . We assumed the local \mathbf{H} and \mathbf{B} vectors to always be collinear, and a scalar treatment of the $\mathbf{H}(\mathbf{B})$ relation was considered. Following the fixed point (FP) technique, the relation between \mathbf{H} and \mathbf{B} is expressed as $\mathbf{H}(\mathbf{B}) = \nu_T \mathbf{B} + \mathbf{R}$. The coefficient ν_T is related to the slope of the initial magnetization curve and is held constant throughout the calculation. The residual term \mathbf{R} is iteratively evaluated, starting from a trial value.

Under periodic conditions, the problem is formulated in the frequency domain, introducing a set of complex vector potential harmonics $\mathbf{A}^{(n)}$, where n is the harmonic order corresponding to the angular frequency $n\omega$. The application of the iterative FP scheme to Eq. (1) leads to a sequence of linear problems, having the form

$$\begin{aligned} \nabla \times (\nu_T \nabla \times \mathbf{A}_k^{(n)}) = & -i\omega n \sigma \mathbf{A}_k^{(n)} + i\omega n \frac{\sigma}{S} \int_{\Omega} \mathbf{A}_k^{(n)} dS' \\ & - \nabla \times \mathbf{R}_{k-1}^{(n)}, \end{aligned} \quad (2)$$

where k is the iteration index. The problem is unidimensional, since any quantity depends only on the depth x across the lamination thickness. Following FEM, the lamination is subdivided into a conveniently high number (~ 100) of lay-

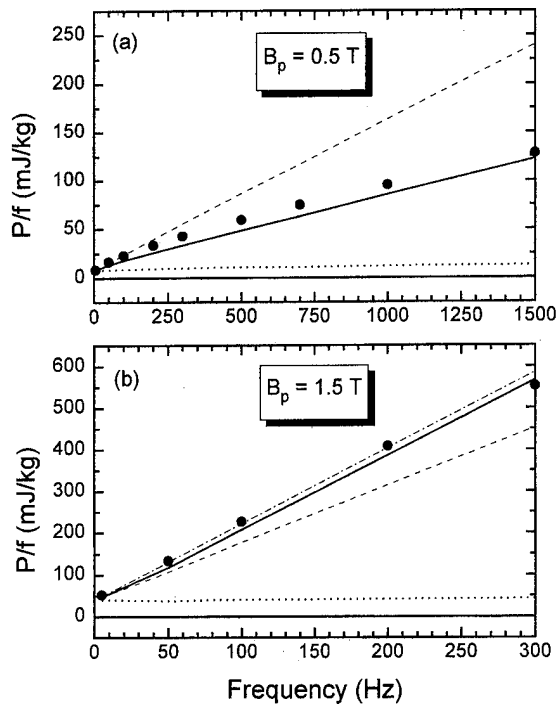

FIG. 1. (a) Energy loss vs frequency at $B_p=0.5$ T. Points: experiments; dotted line: computed hysteresis loss; continuous line: computed total loss; dashed line: total loss obtained by adding to the hysteresis loss the standard classical expression holding in the absence of skin effect. (b) Same for $B_p=1.5$ T. Dash-dotted line: analytical prediction obtained by assuming $B=+B_p$ when $H>0$, $B=-B_p$ when $H<0$.

ers and on each layer the solution is interpolated by means of first order shape functions. It is worth noting that the FP iterations change only the right-hand side of Eq. (2), without requiring any modification of the stiffness matrix.

At each iteration step, all the harmonic components of the vector potential \mathbf{A} are calculated, providing the corresponding components of the magnetic induction $\mathbf{B}=\nabla\times\mathbf{A}$. The time behavior of \mathbf{B} is obtained by an inverse fast Fourier transform of the harmonic components. The $\mathbf{H}(\mathbf{B})$ dependence is described through PM, used in a reversed fashion,³ in order to compute the local field wave form $\mathbf{H}(\mathbf{t})$ that generates the known local \mathbf{B} wave form. Once the \mathbf{B} and \mathbf{H} wave forms are known, the time evolution of the residue \mathbf{R}_k is computed over each element, the harmonic decomposition is performed again and the right-hand side of Eq. (2) is upgraded. The computation scheme is iterated until convergence.

For any given solution, the total loss was calculated by taking the time integral of the field at the lamination surface times the mean induction rate, i.e., averaged over all mesh elements. The hysteresis loss was instead calculated by taking the time integral of $\mathbf{H} d\mathbf{B}$ in each mesh element and integrating the result over the whole lamination volume. Classical losses can be also evaluated by integrating the quantity J^2/σ in space and time, where the current density \mathbf{J} is evaluated from the vector potential \mathbf{A} . The comparison between the total loss and the sum of the hysteresis and classical losses provided an additional check of the computation accuracy.

FIG. 2. Computed profiles of the peak induction vs lamination depth at different exciting frequencies for macroscopic peak induction $B_p=0.5$ and 1.5 T.

The switching field Preisach distribution used to characterize the material was assumed to have the factorized form $p(\alpha,\beta)=f(\alpha)f(-\beta)$, which is the natural factorization expected in soft magnetic laminations.⁵ $p(\alpha,\beta)$ was reconstructed, as suggested in Ref. 6, from the recoil curve of the loop measured at peak induction $B_p=1.7$ T. The obtained distribution function $p(\alpha,\beta)$ was found to be sharply peaked at low (α,β) values, as expected from the shape of the experimentally determined static hysteresis loops. In order to efficiently handle the numerical problem, the Preisach plane was covered with a mesh having increased density in the region where the peak of $p(\alpha,\beta)$ was located.

III. EXPERIMENTAL RESULTS AND DISCUSSION

Dynamic hysteresis loops and power losses were measured by a digital feedback wattmeter which allows one to carry out measurements under controlled induction wave form in a wide frequency range (0.5 Hz–100 kHz).⁷ Static hysteresis loops and the normal magnetization curve were determined by means of a precision ballistic setup. Experiments were performed on 2 wt % Si–Fe alloys. Laminations 1 mm thick were tested as 30×300 mm strips, inserted in an Epstein frame with a reduced number of turns.

FIG. 3. Experimental and computed hysteresis loops for $B_p=0.5$ T. Lines: measurements (dashed: $f=300$ Hz, continuous; $f=1.5$ kHz). Symbols: theoretical prediction.

FIG. 4. Instantaneous profiles of the induction $B(x)$ at different times t along the period T , at $f=300$ Hz and macroscopic peak induction $B_p=1.5$ T. A: $t=0$; B: $t=T/8$; C: $t=T/4$; D: $t=3T/8$; E: $t=T/2$.

The loss per cycle vs frequency at 0.5 T is shown in Fig. 1(a). The continuous line represents the FEM calculated total loss, while the dotted line is the hysteresis loss, obtained from the integral of local $\mathbf{H} \cdot d\mathbf{B}$ over time and over the mesh elements. The calculations show that the hysteresis loss, which would be independent of f in the absence of any skin effect, increases with frequency, because of the nonconstant peak induction profile vs lamination depth. The dashed line represents the sum of the hysteresis loss and the standard classical loss $P_c/f = (\pi^2/6)\sigma d^2 B_p^2 f / \delta$ (d is the lamination thickness and δ is the mass density). As expected, this law gives a grossly overestimated total loss figure in the frequency range where the skin effect becomes important. This is well illustrated by Fig. 2, which shows the FEM calculated frequency dependence of the peak induction profiles vs lamination depth. Above a few hundred Hz, about half of the lamination becomes flux depleted, an effect compensated by the strong increase of $B_p(x)$ near the surface. The measured and calculated hysteresis loops at 300 Hz and 1.5 kHz are shown in Fig. 3. At low f , some disagreement between the predicted and measured loop shapes was found. This is likely due to limitations in the identification of the Preisach distribution, which was based on data at 1.7 T only.

The loss behavior at 1.5 T shows that, with the increase of the macroscopic peak induction, the slope of the experimental P/f vs f curve suffers a progressive increase, which is correctly predicted by the model [see Fig. 1(b), and Fig. 4 for the loop shapes]. The loss values obtained by both measurements and FEM calculations are larger than the ones calculated through the standard classical loss expression given above, just the opposite of what was observed at 0.5 T. This difference is the consequence of the qualitatively different flux penetration pattern in the lamination. As shown in Fig. 2, the peak induction attains quite a uniform profile over the lamination cross section. But such a peak value is reached at different times for different depths (see Fig. 5) and it is this phase difference that causes additional inhomogeneities in the magnetization rate spatial distribution and ensu-

FIG. 5. Experimental and computed hysteresis loops for $B_p=1.5$ T. Lines: measurements (dashed: $f=50$ Hz, continuous: $f=300$ kHz). Symbols: theoretical prediction.

ing higher losses. Some useful information on this behavior can be obtained analytically, without resorting to FEM calculations. In fact, when B_p is comparable with the saturation magnetization and the dynamic fields involved in the problem are much larger than the material coercivity, the $\mathbf{B}(\mathbf{H})$ relation can be approximated by a step function of the form $B = +B_p$ when $H > 0$, $B = -B_p$ when $H < 0$. In this case, the flux and field distribution inside the lamination can be calculated analytically, and the loss turns out to be equal to $(4/3)P_c$, where P_c is the standard expression given above.

IV. CONCLUSIONS

The present calculations predict hysteresis and classical losses, but not excess losses due to magnetic domain effects. From the quantitative point of view, this is not expected to lead to important errors in the steel here considered, where the excess loss plays a minor role due to the fine grain size, but it might become relevant for those laminations where the grain size exceeds values of the order of 100 μm . In cases of interest, one can include domain effects into the treatment by considering the so-called dynamic Preisach model, as recently proposed by some authors.⁴ This model is equivalent to introducing a local $\mathbf{B}(\mathbf{H})$ relationship which depends not only on the \mathbf{H} history, but also on the field rate $d\mathbf{H}/dt$. The use of the dynamic Preisach model would not require any substantial change in the design of the FEM algorithm presented here. The main difference is likely to be the drastic increase of the computation time, as a consequence of the complex internal structure of the dynamic Preisach model.

High temperature magnetic properties of 49%Co–2%V–Fe alloy

Lin Li

Research and Development Center, Carpenter Technology Corporation, Reading, Pennsylvania 19612-4662

Direct current hysteresis loops of 49%Co–2%V–Fe alloy have been measured at temperatures up to 800 °C. Two phase structure is evident in the B – H loops between 580 and 730 °C. This alloy cannot be reliably operated above 580 °C. The second magnetic phase is believed to result from the nucleation and growth of disordered α phase in the ordered α' phase matrix. Magnetic properties (measured as B at $H=2.5$ and 10 Oe) degrade with time during aging at 450 °C, but approach stable values after about 1000 h, which provides the possibility for long-term high temperature (e.g., 450 °C) operation if the degraded properties are still acceptable for the application. The coercive field remains unchanged while the permeability decreases irreversibly during aging. The irreversible magnetic property changes that occur during aging at 450 °C are most likely caused by an increase in the long range order parameter. © 1996 American Institute of Physics. [S0021-8979(96)36308-5]

I. INTRODUCTION

Hiperco® Alloy 50 with the composition of 49%Co–2%V–Fe has high saturation induction, high Curie temperature, and low coercive field. Some possible applications for Hiperco Alloy 50 are at temperatures up to 600–800 °C. However, no magnetic property data are available at such high temperatures. Furthermore, these potential applications also raise the question of the stability of this alloy at high temperatures.

Pandey *et al.*¹ have studied the aging behavior of 49%Co–2%V–Fe up to 450 °C. However, the data, for instance, the testing point of permeability μ and the magnetic field strength corresponding to B_m , are not well defined and therefore are difficult to apply in practical design.

In this study, we measured the change in magnetic properties (at various fields) of Hiperco Alloy 50 from 25 to 800 °C, and during long term aging at 450 °C.

II. EXPERIMENT

The specimens used were stamped rings (i.d.=1.25 in., o.d.=1.5 in.) made from a 0.014 in.-thick strip. The rings were heat treated in dry hydrogen at 760 °C for 2 h and cooled at 180 °C/h.

In order to determine magnetic properties at elevated temperatures (500–800 °C), technical difficulties such as insulation of the windings and shielding (used Hiperco Alloy 27 strip in this experiment) against interference from the heating coils had to be overcome.

A stack of about 50 rings was placed in a quartz core box. Nickel wire (24 gauge) coated with ceramic was used for the windings. The magnetization of the Ni wires appears to have no effect on the magnetic measurements. A type- N thermocouple was attached to the ring pack to monitor the specimen temperature. The rings were heated under high purity argon with neither magnetic field nor mechanical stress being applied. The magnetic measurements were made using a Yokogawa dc magnetic hysteresis loop tracer (type 3257). Two separate test fields were used in the aging study, 2.5 and 10 Oe.

III. RESULTS AND DISCUSSIONS

After several initial tests, we realized that two kinds of magnetic property changes occur at high temperature: reversible changes that occur as a function of temperature, and irreversible changes caused by prolonged heating (aging) at a relatively high temperature. The irreversible changes mean that the properties at a given test point and temperature in a heating–cooling cycle will be different from the properties in the previous cycle, even if the cycles are identical. These effects have not been clearly distinguished in prior studies^{1,2} on high temperature magnetic properties. Although it is impossible to separate these two changes completely, the measured changes are fairly reversible at temperatures lower than 450 °C and for short heating times, i.e., less than 15 min, as shown in Table I. However, we observed a large irreversible change in B at temperatures above 450 °C even with short heating times.

Figure 1 shows the B – H loops of specimen B in Table I held at elevated temperatures for short times. As the temperature is increased to 580 °C, the B – H loop becomes more square and starts to show small irregularities, as indicated by arrows. These irregularities become larger at 650–700 °C but disappear above 730 °C. Hiperco Alloy 50 has an order–disorder transition at about 730 °C.³ It is reasonable to assume that these irregularities result from the nucleation and growth of the disordered α phase in the matrix of ordered α' phase. This was confirmed by observation of a smooth B – H loop at temperatures above 730 °C when the $\alpha' \rightarrow \alpha$ transition is complete and only the single phase α exists.

Long-term operation of the alloy above 580 °C is not recommended due to the irregularities in the B – H loops. However, high temperature (e.g., 450 °C) operation may still be possible provided the limited magnetic property deterioration can be tolerated. Figure 2 shows the change in magnetic induction B versus aging time. The reversible change in B is shown at the initial point, i.e., at aging time=0, compare $B_{25\text{ °C}}$ to $B_{450\text{ °C}}$. The induction B then continues to decrease (irreversible change portion) as aging proceeds. This irreversible change is the greatest in the first 200 h, and B stabilizes after about 1000 h. Actual applications have complicated heating cycles but the peak temperature can be

TABLE I. Magnetic property changes of Hiperc Alloy 50 during the first rapid heating-cooling cycle. Each temperature was held for 15 min and each $B-H$ loop measurement took 30 s.

Test temp.	Specimen A $H_m=2.5$ Oe			Specimen A $H_m=10$ Oe

determined. The curves in Fig. 2 define the minimum values for B at 2.5 and 10 Oe after the material has been exposed at peak temperatures up to 450 °C. The value of H_c remains unchanged (1.4 Oe) during the entire aging process at 450 °C.

After aging at 450 °C for 1150 h, the specimen was cooled to 25 °C and the $B-H$ curve determined again. Notice that in Fig. 2 the differences between $B_{25^\circ\text{C}}$ and $B_{450^\circ\text{C}}$ at the beginning and the end of the aging cycle are fairly similar. That is to say, the reversible B change remains rela-

FIG. 1. $B-H$ loops of Hiperc Alloy 50 at elevated temperatures ($H_m=5$ Oe). Arrows indicate the irregularities caused by nucleation and growth of disordered α phase in the ordered α' phase.

FIG. 2. Induction B change during aging of Hipercor Alloy 50 at 450 °C.

tively constant during the aging cycle.

In Fig. 3, loops A and B show the decrease in permeability after aging at 450 °C. The decrease in B is less severe at higher magnetic fields. This permeability decrease can be recovered to a great extent by a normal heat treatment, as loop C shows.

X-ray diffraction and transmission electron microscopy results did not show any major metallurgical structure changes in the specimens after aging. Therefore, we believe that the irreversible property change during aging is mainly caused by the change in the long range ordering parameter.

Effect of nucleating layers on the soft magnetic properties of multilayer permalloy films

Craig A. Grimes

Department of Electrical Engineering, The University of Kentucky, Lexington, Kentucky 40506

The effects of different undercoats and silicon nitride nucleating layers on the coercive force, anisotropy field, and 5 to 100 MHz complex permeability spectra of magnetically soft, $\text{Ni}_{81}\text{Fe}_{19}$ multilayer thin films sputtered onto flexible, 52- μm -thick polyethylene terephthalate substrate for use as identification markers or electromagnetic interference shields is reported. In comparison to films deposited directly onto the substrate, nonmagnetic undercoat layers, including aluminum, copper, silicon, and silicon nitride, are found to increase the soft magnetic properties of subsequently deposited films. Nucleating layer effects are dependent upon the undercoat/nucleating layer combination. © 1996 American Institute of Physics. [S0021-8979(96)36408-1]

I. INTRODUCTION

Sputter deposition of thin films onto flexible, thin, polymeric-type substrates is currently an area of considerable interest¹⁻³ for fabrication of sensors, identification markers, and films for the control of electromagnetic interference (EMI). This work focuses on the deposition of magnetically soft, multilayer thin films onto 52- μm -thick polyethylene terephthalate (PET) substrates that can be used as identification markers or for the control of EMI. The commercial significance of these products to the magnetics community is significant. For example, the European retail market has a current annual consumption of approximately 320 million magnetically soft thin film antitheft markers, each approximately 1 μm thick and 3 cm^2 in size, made by sputter deposition onto flexible webs of PET approximately 50 μm thick using roll to roll winding. Films used for identification markers require a low coercive force, and a complex permeability spectra, $\mu = \mu' - j\mu''$, where μ' is large and μ'' small. So that the film does not saturate, films used for control of EMI must have a coercive force larger than the field strength of the incident magnetic field, and a large permeability magnitude over the frequency range of interest.

Although sputtering allows for fabrication of a magnetically soft film, sputtering a film onto a thin polymeric-type sheet is difficult due to the topology of the substrate-film interface; the incident sputtered atom melts the substrate on a microscale dimension, resulting in an initial nucleation layer containing hydrocarbons that affect film performance. Polyimide substrates, such as kapton, are durable, smooth, offer good film adhesion, and have been used in earlier work,^{1,2} but are too expensive for use in large volume manufacture of identification markers. PET substrates are inexpensive, durable, and offer good film adhesion. In an earlier work,⁴ it was shown that the uniformity of magnetic films sputtered onto untreated PET was quite poor, but could be greatly enhanced by briefly sputter etching the substrate in oxygen prior to film deposition; the incident oxygen ions act to clean the surface and remove asperities or surface irregularities.⁵ It was also found that the soft magnetic properties of a film stack could be enhanced by deposition of an aluminum metal undercoat or barrier layer atop the plastic substrate prior to deposition of the magnetic film.⁴ To clarify the terminology used in this article, an undercoat layer is a homogeneous film

thick enough to totally cover the substrate, generally 100 nm or more, so that the magnetic stack does not come into contact with the hydrocarbons of the substrate. In contrast to the relatively thick undercoat layers, nucleating or seed layers are quite thin, generally less than 15 nm thick, and are therefore nonhomogeneous layers. This article reports on further investigations into the use of different undercoat layers, with and without the use of silicon nitride nucleating layers to enhance the soft magnetic properties of sputter deposited multilayer permalloy films. In earlier work,⁴ it was found that the simplest multilayer stack, deposited onto a flexible PET substrate, for which optimal soft magnetic properties were obtained, i.e., low coercive force and high permeability, consisted of six magnetic layers; therefore a fixed stack geometry of six magnetic layers is used while investigating the effect of undercoat and nucleating layers. The in-plane coercive force H_c , anisotropy field H_k , quasistatic (5 MHz) permeability magnitude $|\mu|$, and the 5 to 100 MHz complex permeability spectra of dc planar magnetron sputtered $\text{Ni}_{81}\text{Fe}_{19}$ multilayer films are measured as a function of undercoat and silicon nitride nucleating layer. The hard-axis permeability spectra are measured using a permeameter;⁶ in-plane H_c and H_k values are measured at 10 Hz using a BH loop.

II. EXPERIMENT

Our choice of substrate is determined by the nature of the end product. EMI shields need to be flexible in order to be incorporated into building supplies, packages, electronic containers, etc. For widespread application identification markers need to be very inexpensive; large scale production requires them to be cut from a large volume, wide web substrate that is as thin as possible. Untreated PET is inexpensive, offers good film adhesion, can be handled easily, and is suitable for deposition of high performance soft magnetic films. Scanning electron microscope (SEM) examination of the untreated PET surface shows a large number of asperities, surface defects, and nonuniformities that result in localized variation of the magnetic properties of subsequently deposited films. It was found that the asperities and defects could be greatly reduced, and the uniformity of subsequently deposited films enhanced, by sputter etching the substrate web in oxygen⁵ at a power level of 3 W/cm^2 for 6 s. Lower

TABLE I. Effect of different 150-nm-thick undercoats. Six 80 nm $\text{Ni}_{81}\text{Fe}_{19}$ layers, five 10 nm, Si_3N_4 spacers.

Undercoat	H_c (Oe)	H_k (Oe)	$ \mu $
No undercoat	0.19	4.6	2600
Silicon nitride	0.10	1.4	3800
Silicon	0.12	3.1	3550
Copper	0.16	3.6	3200
Aluminum	0.12	3.3	3500
$\text{Co}_{79}\text{Cr}_{21}$	>100	>100	5500

power levels resulted in greater levels of nonuniformity, while larger power levels tended to overheat the web which resulted in creases. Therefore, throughout this study the 52- μm -thick PET substrate web was cleaned by sputter etching at the above power level prior to film deposition. Background pressure in the sputtering chamber was 1.8 mTorr, the sputtering gas was argon, and the silicon nitride layers were deposited by sputtering from a silicon target in a nitrogen rich environment.

A. Undercoat layers

It was found earlier⁴ that multilayer magnetic films with silicon nitride spacer layers result in substantially higher permeabilities than spacer layers of either aluminum oxide or silicon. It was also found⁴ that the soft magnetic properties of a film could be enhanced by depositing the films onto an aluminum undercoat that covered the PET substrate. Focusing on Si_3N_4 as the spacer material of interest, the magnetic properties of a multilayer stack were examined as a function of different undercoats. Table I lists the quasistatic magnetic properties of multilayer films consisting of six 80 nm $\text{Ni}_{81}\text{Fe}_{19}$ layers and five 10 nm Si_3N_4 spacer layers, deposited onto different types of undercoats 150 nm thick; the first magnetic layer is deposited directly onto the undercoat. We see that of the undercoats examined, the Al, Cu, Si, and Si_3N_4 undercoats greatly improved the soft magnetic properties of the subsequently deposited films. The largest permeability value measured was with the 150 nm hcp oriented thick $\text{Co}_{79}\text{Cr}_{21}$ undercoat; the measured permeability spectra is shown in Fig. 1. Although the permeability of the films deposited onto the CoCr undercoat are quite high, indicative of a small anisotropy field value, there are no signs of a resonance usually associated with high permeability/low anisotropy films.

It was reported by Nakagawa *et al.*⁷ that a very thin, approximately 10 nm, undercoat of $\text{Co}_{79}\text{Cr}_{21}$ sputter deposited onto polyethylene naphthalate (PEN) tape, greatly improved the crystalline structure of a subsequently deposited $\text{Ni}_{81}\text{Fe}_{19}$ layer, which has been shown by Ohji *et al.*⁸ to play a significant role in the fabrication of a high permeability film. It was not possible to measure either H_c or H_k of the film deposited atop the CoCr undercoat since the BH loop measurements appeared to be dominated by the magnetically hard undercoat, the values of which were beyond the 100 Oe limit of the BH loop. The origin of such high permeability values in connection with large H_c and H_k values imposed by the CoCr undercoat is not yet understood, and the subject

FIG. 1. Complex permeability spectra of six 80 nm $\text{Ni}_{81}\text{Fe}_{19}$ layers and five 10 nm Si_3N_4 spacer layers, on top of a 150 nm $\text{Co}_{21}\text{Cr}_{79}$ undercoat.

of ongoing research; one possibility is that the stray fields of the CoCr undercoat act to align the magnetization vector of the subsequently deposited soft magnetic layers. The CoCr undercoats in this work are much thicker than those used by Nakagawa *et al.*,⁷ although Nakagawa did not make any magnetic measurements, studying only the crystalline structure, as the undercoat layer decreases in thickness the stray field will become weaker, and hence the measured H_c and H_k values of the subsequently deposited films more permalloy like. It is possible that, like the films of Ohji *et al.*,⁸ the CoCr acts to orient the permalloy into a high permeability crystalline structure; we will address this point further in the discussion of nucleating layers.

Since high permeability values were obtained using a CoCr undercoat, the combined use of CoCr as an undercoat and spacer layer material was examined. Table II summarizes the 5 MHz permeability magnitude $|\mu|$ data for multilayer films consisting of six 80 nm permalloy layers, with CoCr spacers 10 or 30 nm thick, deposited on top of CoCr undercoats 150 or 300 nm thick. The combined use of a CoCr undercoat and spacer layer results in a lower permeability film than use of a CoCr undercoat alone.

B. Nucleating layers

Exclusive of the affects of undercoat layers, which are thick enough to be homogeneous, very thin nonhomogeneous layers of material, denoted as "seed" or "nucleation" layers, can be used to alter the properties of subsequently deposited magnetic films; see, e.g., Refs. 7 and 9. Since undercoat layers were shown to enhance the soft magnetic properties of subsequently deposited films we combined undercoat layers with nucleation layers to see how soft mag-

netic properties could be further enhanced or controlled. Table III summarizes the effect of a 10 nm silicon nitride nucleating layer, in combination with the different undercoats previously examined, on the quasistatic magnetic properties of multilayer films consisting of six 80 nm Ni₈₁Fe₁₉ layers and five 10 nm silicon nitride spacer layers. The silicon nitride nucleating layer has made no apparent affect on the films deposited upon the silicon nitride undercoat. The nucleating layer has made the films deposited upon the copper, aluminum, and silicon undercoats magnetically softer, decreasing the coercive force and anisotropy field, and increasing the low frequency permeability. The nucleating layer has also increased the soft magnetic properties of films deposited without benefit of an undercoat. The nucleating layer has caused a dramatic drop in the permeability of the multilayer film on top of the CoCr undercoat layer. Since the thickness of the nucleating layer is too thin to affect coupling of the CoCr stray field with the subsequently deposited permalloy layers, it appears that the decrease in permeability due to the silicon nitride nucleating layer has its origin in the growth induced microstructure of the permalloy film;⁸ this issue will be addressed in future work.

III. CONCLUSIONS

The coercive force, anisotropy field, and the 5 MHz permeability magnitude of multilayer films deposited onto 52- μ m-thick PET webs, for use as identification markers or EMI shields, are examined as a function of undercoat and silicon nitride nucleating layer. It is found that nonmagnetic undercoats including aluminum, copper, silicon, and silicon nitride improve the soft magnetic properties of subsequently deposited films; the films deposited on top of the silicon nitride undercoat demonstrated the lowest coercive force and anisotropy field values. Silicon nitride undercoats had a tendency to flake. Silicon undercoats were much more durable than the silicon nitride undercoats, but did demonstrate a small amount of flaking. Aluminum and copper undercoats were deposited to thicknesses of 2 μ m without ductility or adhesion problems. A Co₇₉Cr₂₁ undercoat resulted in the highest

permeability values; although the permeameter measurement was able to determine the permeability, the coercive force and anisotropy field could not be measured as those values were beyond the field strength of the *BH* loop. The high permeability of the films deposited on top of the Co₇₉Cr₂₁ undercoat is indicative of a magnetically soft film. However the high coercive force and anisotropy field values, greater than the 100 Oe limit of the *BH* loop, stand in contradiction to the apparent magnetic softness indicated by the high permeability. The combination of high permeability and large anisotropy field is not to be expected, and will be the subject of further examination.

When used with a silicon, aluminum, or copper undercoat silicon nitride nucleating layers are found to enhance soft magnetic properties. When the CoCr undercoat was used with a 10 nm silicon nitride nucleating layer the film permeabilities were rather low, falling to approximately half that obtained with just the CoCr undercoat. This result, in agreement with earlier work,⁸ indicates that the hcp CoCr acts to orient the permalloy into a high permeability regime which the very thin silicon nitride layer is able to disrupt.

The Mössbauer effect spectra of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$, which have been measured between 85 and 295 K, indicate the presence of a spin reorientation of the iron magnetic moments at 105 ± 5 K. At this magnetic transition a large increase of ~ 50 kOe in the $6c$ iron magnetic hyperfine field and abrupt changes in all of the remaining hyperfine fields are observed. A study of the changes in the quadrupole shifts at the transition indicates that this spin reorientation takes place within the basal plane of this rhombohedral compound. As expected, the temperature dependence of the isomer shifts does not show any anomaly at the transition. The origin of this spin reorientation is attributed to competing effects between lattice expansion upon deuteration and lattice contraction upon cooling.

I. INTRODUCTION

As Coey and Sun¹ first showed in 1990, insertion of nitrogen into R_2Fe_{17} , where R is a rare earth, improves their magnetic properties and dramatically increases their Curie temperatures. We have previously studied^{2,3} the Mössbauer spectra of $\text{Pr}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}\text{N}_{2.6}$ and the hydrides of $\text{Nd}_2\text{Fe}_{17}$. Hence, it is useful to study the deuterides of $\text{Pr}_2\text{Fe}_{17}$ and to compare their Mössbauer spectral properties with those of the nitride, $\text{Pr}_2\text{Fe}_{17}\text{N}_{2.6}$, and the related hydrides. In this article, we will report the interesting and unexpected behavior of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$. $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ will be discussed in a future article⁴ along with various other deuterides and hydrides of R_2Fe_{17} .

II. EXPERIMENT

$\text{Pr}_2\text{Fe}_{17}\text{D}_3$ was prepared as described⁵ earlier and its deuterium content is known to an accuracy of $\sim 3.0 \pm 0.1$. Mössbauer absorbers of 36 mg/cm^2 thickness were prepared from powdered samples which had been sieved to a 0.045 mm or smaller diameter particle size. Mössbauer spectra were obtained between 85 and 295 K on a constant-acceleration spectrometer which utilized a rhodium matrix cobalt-57 source and was calibrated at room temperature with α -iron foil. The resulting spectra have been fitted as discussed below and the estimated errors are at most ± 1 kOe for the hyperfine fields, $\pm 0.005 \text{ mm/s}$ for the isomer shifts, and $\pm 0.01 \text{ mm/s}$ for the quadrupole shifts.

III. MÖSSBAUER SPECTRAL RESULTS

The Mössbauer spectra of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$, obtained between 85 and 295 K, are shown in Fig. 1. It is immediately apparent that dramatic changes occur in the spectra between 95 and

120 K. A closer examination of the spectra indicates that between 120 and 295 K they are similar but different from those obtained below 95 K. Additional spectra obtained between 95 and 120 K show a superposition of the high and low temperature spectra.

Because in both $\text{Pr}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}\text{D}_5$, the magnetic moments are oriented⁵ ferromagnetically in the basal plane of the $\text{Th}_2\text{Zn}_{17}$ rhombohedral unit cell, we assume that the magnetic moments in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ have the same orientation. Because of this basal orientation of the moments and because of the point symmetry of the four iron crystallographic sites in the $\text{Th}_2\text{Zn}_{17}$ structure, the spectra were fitted² with seven sextets, with relative areas of 6:6:3:12:6:12:6, for the seven magnetically inequivalent, $6c$, $9d_6$, $9d_3$, $18f_{12}$, $18f_6$, $18h_{12}$, and $18h_6$ sites. The constraints applied to the hyperfine parameters have been described in detail elsewhere.² The most important constraint is that the isomer shifts of crystallographically equivalent, but magnetically inequivalent, sites be equal. Furthermore, all lines in a spectrum have been fit with a single linewidth, of between 0.28 and 0.30 mm/s. Finally, a sextet corresponding to α -iron with a relative area of $\sim 5\%$ was required to fit the observed spectra.

Figure 2 shows the temperature dependence of the four site averaged hyperfine fields. Clearly between 120 and 95 K there is a large increase of ~ 50 kOe in the $6c$ magnetic hyperfine field and there are abrupt changes in all of the remaining hyperfine fields. These changes indicate the presence of a magnetic transition in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ at 105 ± 5 K. The nature of this transition, which does not show any obvious hysteresis, may be elucidated through the study of the quadrupole shifts, as discussed below.

The weighted average hyperfine fields are larger than those found in $\text{Pr}_2\text{Fe}_{17}$ but smaller than those found in $\text{Pr}_2\text{Fe}_{17}\text{N}_{2.6}$ at the corresponding temperatures.² This trend parallels the evolution of the magnetic moment^{2,5} upon hy-

^{a)}Also at: Institut Laue Langevin.

FIG. 1. The Mössbauer spectra of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ obtained at the indicated temperatures.

drogenation and nitrogenation. The hyperfine fields at the four crystallographic iron sites decrease in the order $6c > 9d > 18f > 18h$, an order previously observed^{2,6-8} in the R_2Fe_{17} compounds, where R is Pr, Nd, Sm, Ho, and Th, and an order which agrees with the decreasing number of iron near neighbors for each site.

The spectra of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ in both magnetic states are different from those of $\text{Nd}_2\text{Fe}_{17}\text{H}_3$. This difference indicates that the orientation of the magnetic moments within the basal plane is different in the two compounds, a difference already noted² for $\text{Pr}_2\text{Fe}_{17}$ and $\text{Nd}_2\text{Fe}_{17}$. The weighted average hyperfine fields in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ at 155, 225, and 295 K are ~ 5 kOe smaller than those observed³ at the same temperature in $\text{Nd}_2\text{Fe}_{17}\text{H}_3$. In contrast, the weighted average hyperfine field at 85 K is 15 kOe larger. Hence, the magnetic transition which occurs in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ at ~ 105 K increases the low temperature average magnetic moment above the value in $\text{Nd}_2\text{Fe}_{17}\text{H}_3$.

FIG. 2. The temperature dependence of the hyperfine fields in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$.

Figure 3 shows the temperature dependence of the isomer shifts of the four crystallographically distinct iron sites and their weighted average. It is clear that none of the isomer shifts, nor their weighted average, show any anomaly in their

FIG. 3. The temperature dependence of the four isomer shifts in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ and their weighted average.

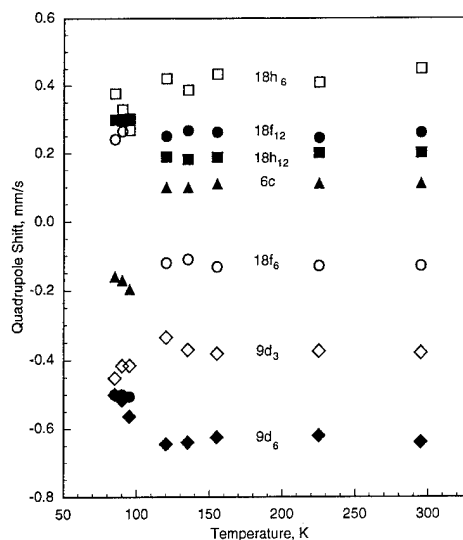

FIG. 4. The temperature dependence of the seven quadrupole shifts in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$.

temperature dependence around 105 K. Of course, no anomaly in the isomer shift would be expected at a magnetic transition. This behavior supports our fitting model both above and below the magnetic transition. The slopes of the straight lines in Fig. 3 range between -5.85×10^{-4} and -8.30×10^{-4} mm/(s K) and are similar to those measured² in $\text{Pr}_2\text{Fe}_{17}$.

The weighted average isomer shift of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ is larger than that of $\text{Pr}_2\text{Fe}_{17}$ at the same temperature in agreement with the unit cell expansion upon deuteration. A similar increase of ~ 0.05 mm/s was observed³ upon hydrogenation of $\text{Nd}_2\text{Fe}_{17}$. The correlation between the Wigner-Seitz cell volume and the isomer shift for each iron site in going from $\text{Pr}_2\text{Fe}_{17}$ to $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ shows a behavior similar to that observed for $\text{Nd}_2\text{Fe}_{17}$ and $\text{Nd}_2\text{Fe}_{17}\text{H}_3$ and will be discussed in detail elsewhere.⁴

Figure 4 shows the temperature dependence of the seven quadrupole shifts in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$. It is immediately apparent that at the magnetic transition at 105 K the quadrupole shifts of the 6c and 18f sites change sign and that those of the 9d and 18h sites change their values. These abrupt changes cannot result from a sudden change in the electric field gradient value, because no change in crystallographic structure is observed⁹ at low temperature. Hence, they can only result from a change in the angle between the hyperfine field and the principal axis of the electric field gradient tensor, or, in other words, a change in the direction of the magnetic moments at 105 ± 5 K. In $\text{Pr}_2\text{Fe}_{17}$, the magnetic moments are believed^{10,11} to lie along the *b* axis or $[1, -1, 0]$ in the basal plane of the unit cell. Because the signs of the quadrupole shifts of the 6c, 18f, and 18h sites are the same in $\text{Pr}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ above 105 K, we conclude that the moments lie along the *b* axis in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ in the high temperature magnetic phase. Because the spectra below 105 K are still well fit with seven sextets, the magnetic moments still lie in the basal plane but the changes in quadrupole shifts at the magnetic transition indicate that the moments have rotated within the basal plane. Unfortunately, it is not possible to deduce the direction of the moments from the values of the

quadrupole shifts. The measurement of a Mössbauer spectrum above the Curie temperature of $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ may help to solve this question, if the compound does not lose deuterium upon heating and if the spectrum shows enough resolution to permit a reliable fit with four doublets.

The magnetic anisotropy in the R_2Fe_{17} compounds is determined¹² by the rare-earth single ion anisotropy through the interaction between the aspherical crystal field potential at the rare-earth sites and the aspherical charge density of the rare-earth 4*f* shell, described by the Stevens coefficients of the second, fourth, and sixth order, α_J , β_J , and γ_J . The Stevens coefficients are characteristic of the rare-earth atom and do not vary with temperature. Hence, the spin reorientation in $\text{Pr}_2\text{Fe}_{17}\text{D}_3$ at 105 K can only result from changes in the crystal field potential, changes probably resulting from the competing effects of lattice expansion, atomic rearrangement upon deuteration, and lattice contraction upon cooling. No similar spin reorientation was observed³ in $\text{Nd}_2\text{Fe}_{17}\text{H}_3$, between 85 and 295 K, but, of course, it could occur below 85 K and Mössbauer measurements between 4.2 and 85 K will be carried out in the near future to check this possibility. However, it is known^{6,10,11} that the magnetic moments in $\text{Nd}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}$ lie in different directions in the basal plane, probably because the sixth order Stevens coefficients γ_J have different signs. Because the three deuterium atoms are located in the basal plane, they may change dramatically the high order crystal field terms and, in particular, the sixth order term γ_J . Mössbauer spectroscopy is a unique technique to observe this spin reorientation because of its sensitivity to the quadrupole shift. Such a spin reorientation within the basal plane cannot be observed by powder neutron diffraction.

F. Grandjean

Institut de Physique, Université de Liège, B-4000 Sart-Tilman, Belgium

Three samples of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_x$, with x equal to 0.0, 0.3, and 2.8, with the $\text{Th}_2\text{Zn}_{17}$ -type rhombohedral structure, have been studied by powder x-ray and neutron diffraction, magnetic measurements, and Mössbauer spectroscopy. $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ were synthesized by induction melting stoichiometric amounts of the constituent elements, whereas $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ was synthesized by methane-derived gas phase insertion of carbon into finely ground $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ at 600 K. The neutron diffraction determined titanium site occupancies are similar in both $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ in which titanium preferentially occupies the 6c transition metal site. In contrast, the titanium occupancies in $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ are markedly different in that titanium avoids the 6c transition metal site and randomly occupies the other three transition metal sites. This difference in occupancies most likely occurs because the titanium diffusion rate during the quenching of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ is affected by the presence of carbon in the melt. Even though the unit cell volume of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ is larger than that of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$, the 615 K Curie temperature of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ is much lower than the 746 K Curie temperature of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$. This is an indication that the volume expansion, which occurs upon nitrogeneration of R_2Fe_{17} , is not the only factor which contributes to the increase in the Curie temperature. The Mössbauer spectra of $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ confirm the high preferential titanium occupancy of the 6c site. At 85 K the weighted average hyperfine field of $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ is approximately 263 kOe, a value which is 33 kOe smaller than that in $\text{Nd}_2\text{Fe}_{17}$. The 85 K Mössbauer spectrum of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ is virtually identical to that of $\text{Nd}_2\text{Fe}_{17}$ and indicates an approximately random titanium occupancy of the four transition metal sites. © 1996 American Institute of Physics. I. INTRODUCTION

The discovery¹ that the addition of interstitial nitrogen dramatically increases the Curie temperature of R_2Fe_{17} and changes the magnetocrystalline anisotropy from basal in $\text{Sm}_2\text{Fe}_{17}$ to axial in $\text{Sm}_2\text{Fe}_{17}\text{N}_3$ has led to a renewed interest in the R_2Fe_{17} compounds. Even though the Curie temperatures¹ of the resulting $\text{R}_2\text{Fe}_{17}\text{N}_x$ compounds are significantly higher than those of the $\text{R}_2\text{Fe}_{14}\text{B}$ compounds, they are lower than those of the previous generation of permanent magnets based on SmCo_5 . However, the interstitially modified $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ and $\text{Sm}_2\text{Fe}_{17}\text{N}_x$ compounds have high energy products,² approximately 80 kJ/m³, at room temperature and Curie temperatures high enough to make them useful in a wide variety of magnetic applications. Unfortunately, interstitial $\text{R}_2\text{Fe}_{17}\text{N}_x$ and $\text{R}_2\text{Fe}_{17}\text{C}_x$, prepared by gas-solid reactions, are thermally unstable, decomposing at temperatures slightly above their Curie temperatures.³ In contrast, recent studies^{4,5} have shown that certain $\text{R}_2(\text{Fe},\text{M})_{17}\text{C}_x$ solid solutions, where M is Ga, Al, or Si, which were synthesized by a solid-solid reaction, exhibit high thermal stability. In this article we report the results of a crystallographic and magnetic study of three $\text{Nd}_2\text{Fe}_{16}\text{TiC}_x$ samples, with x equal to 0.0, 0.3, and 2.8.

II. EXPERIMENTAL METHODS

$\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ were prepared from 99.9% pure elements by induction melting followed by annealing at 950 °C for 120 h. $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ was synthesized by methane-derived gas phase insertion of carbon into finely ground $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ at 600 K. The phase purity of the samples was checked by x-ray diffraction with Cu K_α radiation on a Philips PW 1800/10 x-ray diffractometer equipped with a single crystal graphite monochromator. The Curie temperatures of the samples were measured by a SQUID magnetometer. The powder neutron diffraction patterns were measured in thin walled vanadium containers in approximately 24 h each at 295 K with 1.4766 Å neutrons, and were refined by the Rietveld method on the basis of the $\text{Nd}_2\text{Fe}_{17}$ structure.⁶ The titanium and carbon site occupancies refined to an accuracy of approximately $\pm 2\%$.

The Mössbauer spectra were measured at 85 and 295 K on a constant acceleration spectrometer which utilized a room temperature rhodium matrix cobalt-57 source and was calibrated at room temperature with α -iron foil. The typical linewidth of the outer lines of α -iron was 0.26 mm/s. Mössbauer absorbers, with a typical thickness of 30 mg/cm², were prepared from powders which had been sieved to a 0.038 mm or smaller particle diameter. The spectra were fitted with

FIG. 1. X-ray diffraction patterns of (a) $\text{Nd}_2\text{Fe}_{16}\text{Ti}$, (b) $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$, and (c) $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$.

seven magnetic sextets corresponding to the seven magnetically inequivalent iron sites expected⁷ for a basal orientation of the magnetization. Details of this fitting procedure have been published elsewhere.^{8,9} The magnetic structures of these $\text{Nd}_2\text{Fe}_{16}\text{TiC}_x$ samples have been determined by neutron diffraction studies¹⁰ to be basal, consistent with the magnetic structures of other $\text{Nd}_2\text{Fe}_{17}$ based interstitial compounds.⁸

III. RESULTS AND DISCUSSION

The Curie temperatures are 380, 440, and 615 K for $\text{Nd}_2\text{Fe}_{16}\text{TiC}_x$ with x equal to 0.0, 0.3, and 2.8, respectively.

X-ray diffraction patterns, see Fig. 1, indicate that the three samples crystallize in the rhombohedral $\text{Th}_2\text{Zn}_{17}$ -type structure. However, a small amount of α -iron is observed in $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$. The lattice parameters, atomic positional parameters, and site occupancies, obtained from the neutron diffraction data, are given in Table I. As can be seen in this table, the replacement of one iron by titanium in $\text{Nd}_2\text{Fe}_{17}$ increases slightly the unit cell volume. A similar small increase has been observed in the $\text{R}_2\text{Fe}_{14-x}\text{Ti}_x\text{B}$ solid solutions.¹¹ However, in contrast, the 857 \AA^3 unit cell volume of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ is much larger than the 802 \AA^3 volume of $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and even larger than the 844 \AA^3 volume¹² of $\text{Nd}_2\text{Fe}_{16}\text{N}_{2.7}$, whereas the 615 K Curie temperature of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ is much lower than the 746 K value¹³ of $\text{Nd}_2\text{Fe}_{17}\text{N}_3$. This indicates that the volume expansion which occurs upon nitrogeneration or carbonation of R_2Fe_{17} is not the only factor responsible for the accompanying increase in the Curie temperature.

As seen in Table I, the titanium site occupancies in $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{C}_{2.8}$ are similar and titanium preferentially occupies the $6c$ transition metal site. In contrast, the titanium site occupancies in $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ are markedly different in that titanium appears to avoid the $6c$ site and almost randomly occupies the other three transition metal sites. The

FIG. 2. The Mössbauer spectra of (a) $\text{Nd}_2\text{Fe}_{16}\text{Ti}$, and (b) $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ obtained at 85 K.

difference in titanium occupancies in the two carbided samples can be attributed to the difference in their preparation. The similar titanium occupancies in $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ are expected because $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ was synthesized by methane-derived gas phase insertion of carbon at 600 K into fine powders of the induction melted $\text{Nd}_2\text{Fe}_{16}\text{Ti}$. Iron and titanium have 12 coordinate metallic radii of 1.26 and 1.47 Å, respectively, and, as a consequence of its larger radius, titanium preferentially occupies the 6c iron site in $\text{Nd}_2\text{Fe}_{17}$, the iron site with the largest Wigner-Seitz cell volume.⁸ None of the metal atoms are appreciably mobile at 600 K and thus the metal occupancies in $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$ are expected and found to be similar. In contrast to the preparation of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$, carbon was present in the melt during the induction melting preparation of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$. Carbon has a very high affinity for titanium and this affinity influences the mobility of the carbon and titanium atoms in the melt.¹⁴ Because of this affinity one expects, as is observed, to find that the titanium prefers the

18f and 18h sites, the sites which have carbon near-neighbors. Consequently, one would expect the titanium occupancies after quenching of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ to be different from those in $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$.

The 85 K Mössbauer spectra of $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ and $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$, see Fig. 2, confirm the difference in titanium occupancies of the 6c transition metal site. In these Mössbauer spectra the highest velocity absorption line is the sixth line of the 6c sextet. As may be seen in Fig. 2, the absorption area of the 6c sextet of the $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ spectrum is smaller than in $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$ and confirms that the titanium 6c occupancy in $\text{Nd}_2\text{Fe}_{16}\text{Ti}$ is higher than in $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$. The weighted averaged hyperfine fields at 85 K are 263, 292, and 254 kOe for the samples with x equal to 0.0, 0.3, and 2.8, respectively. At 295 K, the weighted average hyperfine fields are 189, 191, and 227 kOe, respectively. The dependence of the weighted averaged hyperfine field at 295 K on the carbon content follows that of the Curie temperature. However, $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{0.3}$, whose Curie temperature is much lower than that of $\text{Nd}_2\text{Fe}_{16}\text{TiC}_{2.8}$, has the highest hyperfine field at 85 K.

We report Fe^{57} Mössbauer spectroscopy studies of the effect of carbon doping on the magnetic properties of the Fe sites of $R_2Fe_{17-x}M_xC_y$, and of the presence of multiple phases in these systems. In this study two systems, $Sm_2Fe_{14}Al_3C_y$, where $y=0, 1.0, 2.0$, and 3.0 , and $Nd_2Fe_{14.54}Si_{2.46}C_y$, where $y=0, 0.432$, and 2.544 , were measured at room temperature and analyzed. The ternary compounds $R_2Fe_{17-x}M_xC_y$ studied here have the rhombohedral Th_2Zn_{17} structure with c -axis anisotropy. The Al and Si site occupation used in the fitting were taken from previous results. Analysis of the Mössbauer spectra showed that the hyperfine fields for the different sites decreased in the order $6c, 9d, 18f$, and $18h$. The average hyperfine field for $Sm_2Fe_{14}Al_3C_y$ was found to increase with increasing carbon concentration, which is in qualitative agreement with magnetic measurements. For $Nd_2Fe_{14.54}Si_{2.46}C_y$ the average hyperfine field was found to increase for low C concentration and decrease for high C concentration; this behavior is in agreement with our magnetization measurements. The measured average isomer shift relative to α -iron was found to increase with y . In these compounds alloying with C and/or M can improve the magnetic properties such as Curie temperature and magnetization which make them potential candidates for permanent magnet development. © 1996 American Institute of Physics. I. INTRODUCTION

A large improvement of the hard-magnet properties of Fe-rich intermetallic compounds can be considerably achieved upon introducing nitrogen,¹⁻³ carbon,⁴⁻⁸ or substitutional impurities in the compounds of the type $R_2Fe_{17-x}M_x$ ($R=Ho, Y, Sm, Ce, Pr$, and Nd ; $M=Al, Ga, Si, V, Co$, and Ni).⁹⁻¹⁵ In all these studies the magnetic ordering temperatures were found to increase by substituting other elements for iron or by nitrogenation or carbonation. Wang and Dunlap¹⁶ found that the Curie temperature (T_c) changed from 391 K for Sm_2Fe_{17} to 471 K for $Sm_2Fe_{14}Al_3$. A further increase in T_c can be achieved by adding C or N to these compounds. Shen *et al.*^{17,18} have discovered recently that $Sm_2Fe_{17-x}Ga_xC_y$ can be formed by arc-melting. It is claimed that these materials are more stable at high temperature than those prepared by the gas reaction method. Zheng *et al.*¹⁹ found that T_c goes to 563 K for $Sm_2Fe_{14}Al_3C_3$ which is close to T_c (585 K) for $Nd_2Fe_{14}B$.^{20,21} They found also that the compounds $Sm_2Fe_{14}Al_3C_y$, $0 \leq y \leq 3$, have c -axis anisotropy and the anisotropy field increases from 15 kOe for $y=0$ to more than 100 kOe for $y \geq 2$. Additionally, they found that the magnetization of these compounds increases by a small amount, 96 emu/g for $y=0$ to 100 emu/g for $y=2$, with increasing C concentration.

A neutron diffraction study of $Nd_2Fe_{14.54}Si_{2.46}C_y$, y between 0 and 2.544, by Yelon and Hu²² showed that there are two carbon phases in the sample with $y=2$; one of these phases has low C concentration, $y=0.432$, and the other has high carbon concentration, $y=2.544$; C was found to occupy the $18g$ site for $y=0.432$ and $9e$ site for $y=2.544$. They also found that the fraction of occupancy of Si are 6%, 8%, and

30% for the sites $9d, 18f$, and $18h$, respectively.

In this article we report on Mössbauer experiments for $Sm_2Fe_{14}Al_3C_y$ and $Nd_2Fe_{14.54}Si_{2.46}C_y$ to study the effect of C on the magnetic properties of these compounds. We also use Mössbauer spectroscopy to determine the amount of α -Fe and the presence of multiple phases in these systems.

II. EXPERIMENTAL PROCEDURE

Bulk samples of $Sm_2Fe_{14}Al_3C_y$ with $y=0, 1, 2$, and 3 , were prepared by arc-melting the constituent elements with an Fe-C alloy in a water-cooled copper boat in a flowing argon-gas atmosphere. All the starting elements used were at least of 99.9% purity. The alloys were melted several times to ensure homogeneity. The $Sm_2Fe_{14}Al_3C_y$ samples were wrapped separately in tantalum foil and heat treated in a vacuum at 1100 °C for about 17 h,¹⁹ and subsequently quenched in water.

Samples of nominal composition $Nd_2Fe_{15}Si_2$ were prepared by arc-melting with constituent elements of at least 99.9% purity under an argon atmosphere. For homogeneity, samples were remelted several times. The resulting ingots were vacuum annealed in quartz crucibles at 1000 to 1100 °C for 4 days. Carbide samples were prepared by heating ground powders, $<45 \mu m$ diameter, of the original alloy in methane (CH_4) gas. The system was flushed several times with methane gas to ensure minimum oxygen contamination. The carbide samples were prepared by heating at a rate of 10 °C/min to 500 °C and held for 2 h to allow carbon diffusion into the samples. After carbonation the system was evacuated and held at a temperature above 100 °C to ensure that hydrogen was removed from the system.

FIG. 1. Room temperature Mössbauer spectra of $\text{Sm}_2\text{Fe}_{14}\text{Al}_3\text{C}_y$ compounds. The solid curves represent the fitting.

Room temperature x-ray diffraction measurements on powder samples using a Phillips PWD1710 diffractometer with $\text{Cu } K_\alpha$ radiation showed only the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure with a small amount of α -Fe.

The samples for Mössbauer spectroscopy were prepared by sprinkling a homogeneous thin layer of the powder of the $\text{R}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ compounds on a piece of tape. The samples were studied with a Ranger Mössbauer spectrometer, model MS1200. The velocity drive of this spectrometer operates in the constant acceleration mode. A 35 mCi Co^{57} in Rh γ -ray source was used in this experiment. All the isomer shifts were measured relative to α -iron at room temperature and α -iron, with outer lines width of 0.30 mm/s, was also used for calibration. Some of the samples were found to have a small amount of α -iron, less than 5% in $\text{Sm}_2\text{Fe}_{14}\text{Al}_3\text{C}_y$, 12% in $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}$, and 20% in $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_2$; this component was subtracted from the raw data before the final fitting.

III. RESULTS AND DISCUSSION

Figures 1 and 2 show the room temperature Mössbauer spectra and the fitting (the solid curves) for $\text{Sm}_2\text{Fe}_{14}\text{Al}_3\text{C}_y$ with $y=0, 1, 2$, and 3 and $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_y$ with $y=0$ and 2. The spectra show that the samples are magnetically ordered for all values of y and all of them have different subspectra with different magnetic hyperfine fields. The spectra were fitted with a set of four subspectra, with linewidth of about 0.40 mm/s, because of the c -axis anisotropy, as mentioned by Long *et al.*,²³ which is similar to the models used by Hu *et al.*,²⁴ Long *et al.*,²⁵ and Yelon *et al.*²⁶ for 2:17 compounds. For the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure there are four different iron sites, 6c, 9d, 18f, and 18h, with different environments. Previous Mössbauer measurements by Al-Omari *et al.*^{14,15} for $\text{Sm}_2\text{Fe}_{17-x}\text{Ga}_x\text{C}_y$ and $\text{Sm}_2\text{Fe}_{17-x}\text{Al}_x$, Long *et al.*^{23,25,26} for $\text{Nd}_2\text{Fe}_{17}$ and $\text{Nd}_2\text{Fe}_{17}\text{N}_{2.6}$, Mössbauer and neutron diffraction by Yelon *et al.*²⁷ for $\text{Nd}_2\text{Fe}_{17-x}\text{Al}_x$,

FIG. 2. Room temperature Mössbauer spectra of $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_y$ compounds. The solid curves represent the fitting.

and Mössbauer measurements by Hu *et al.*²⁴ for $\text{R}_2\text{Fe}_{17}\text{N}_{3-\delta}$ showed that the hyperfine fields decrease in the order 6c, 9d, 18f, and 18h. In our fitting and analysis of the data we used the same order.

The relative intensity of various subspectra for different C concentration were the same as of those of $\text{Sm}_2\text{Fe}_{14}\text{Al}_3$ found by Al-Omari *et al.*¹⁵ For $\text{Sm}_2\text{Fe}_{14}\text{Al}_3\text{C}_y$ the hyperfine fields for different sites were found to increase with increasing concentration of C as seen in Fig. 3. The average hyperfine field was found to increase from 198 kOe for $y=0$ to 214 kOe for $y=3$ which is in qualitative agreement with the magnetization measurements by Zheng *et al.*¹⁹ The Curie temperature for these compounds increases with y from 483 K for $y=0$ to 563 K for $y=3$.¹⁹ The increase in the average hyperfine field and in the magnetization must be due to the increase in Curie temperature which is due to the increase in the interatomic exchange interactions upon volume expansion.

For $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_2$ the spectrum was fitted with three phases. The first was $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_{0.432}$, the second was $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_{2.544}$, and the third was FeSi. The first two phases were ferromagnetic with four subspectra, with different isomer shifts, quadrupole shifts, and hyperfine fields, and the third phase was paramagnetic with 5% relative intensity.

FIG. 3. Dependence of the hyperfine field for the different Fe sites of $\text{Sm}_2\text{Fe}_{14}\text{Al}_3\text{C}_y$ on the C concentration y , at $T=295$ K.

FIG. 4. Dependence of the hyperfine field for the different Fe sites of $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_y$ on the C concentration y , at $T=295$ K.

Guided by the results of Yelon and Hu,²² the intensity of the second phase, high C concentration, was twice the intensity of the first phase, low C concentration. The relative intensities of various subspectra for different C concentrations were the same as of those of $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}$ found by Yelon and Hu,²² since we used the same samples. The hyperfine fields for different Fe sites were found to increase for $y=0.432$ and decrease for $y=2.544$ as shown in Fig. 4. The increase of H_{hf} at lower carbon concentration is due to the enhancement of the Curie temperature which shifts the thermomagnetization curve to higher temperature which is similar to previous observations by Shen *et al.*⁵ for $\text{Tm}_2\text{Fe}_{17}\text{C}_x$. The magnetizations for $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_y$ were measured with our magnetometer and found to decrease from 123.2 emu/g for $y=0$ to 118.4 emu/g for $y=2$; this behavior is in agreement with our Mössbauer measurements for the weighted average hyperfine field which decreases from 217 kOe for $y=0$ to 205 kOe for $y=2$.

The average isomer shift ($\overline{\text{IS}}$) relative to α -iron was found to increase by increasing the carbon concentration for both systems: the increase was from -0.04 mm/s for $y=0$ to -0.01 mm/s for $y=3$ in $\text{Sm}_2\text{Fe}_{14}\text{Al}_3\text{C}_y$ and from -0.04 mm/s for $y=0$ to -0.03 mm/s for $y=2.544$ in $\text{Nd}_2\text{Fe}_{14.54}\text{Si}_{2.46}\text{C}_y$. This increase implies a decrease in the s -electron density at the nucleus which can be attributed to the expansion of the cell volume which is similar to the effect of adding nitrogen to the 2:17 compounds as seen by Hu *et al.*²⁴ IS for FeSi was found to be 0.24 mm/s which is in agreement with other values by Shinjo *et al.*²⁸

IV. CONCLUSIONS

Samples of $\text{R}_2\text{Fe}_{17-x}\text{M}_x\text{C}_y$ magnetic compounds have been fabricated and studied by Mössbauer spectroscopy. These compounds have the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure with a small amount of α -Fe impurity. All the samples studied are ferromagnetic and the average hyperfine fields and hence the magnetic moments are found to depend on C concentration in each system. There is a qualitative agreement

between the measured hyperfine fields and the magnetization values. Samples prepared by arc-melting were found to have a single carbon phase, in contrast to those prepared by the gas reaction method, which we and others have found to possess multiple C phases probably due to the different particle sizes. The change in isomer shift with increasing C concentration corresponds to the decreasing s -electron density at the nucleus caused by the volume expansion. The high Curie temperature and uniaxial anisotropy for these compounds with $0 < y < 3$ are promising properties for hard magnets.

We have investigated the effect of substitution and nitrogenation on the hyperfine parameters in $\text{Gd}_2\text{Fe}_{17-x}(\text{Ga},\text{Al})_x$ ($x=1-10$) and $\text{Gd}(\text{Fe},\text{Co})_{12-x}\text{Mo}_x(\text{N}_y)$ ($x=1.5-3.0$ and $y\approx 1$) by means of ^{155}Gd Mössbauer spectroscopy. We have observed marked changes in the values of the electric field gradient V_{zz} , the effective Gd-hyperfine field, and isomer shift. Al substitution in $\text{Gd}_2\text{Fe}_{17}$ leads to a sign reversal of the electric field gradient. No sign reversal of V_{zz} has been observed in the $\text{Gd}_2\text{Fe}_{17-x}\text{Ga}_x$ compounds. The effective hyperfine fields of the $\text{Gd}_2\text{Fe}_{17-x}(\text{Ga},\text{Al})_x$ compounds are decreasing with increasing x , due to the reduction of the $6s$ electron polarization resulting from the decreasing Fe moments. The ultimate value of the isomer shift based on a simple model on chemical effects that would be reached for $x=17$ is 0.52 mm s^{-1} for Al and 0.64 mm s^{-1} for Ga substitution in $\text{Gd}_2\text{Fe}_{17}$, respectively. The electric field gradient of the $\text{GdFe}_{12-x}\text{Mo}_x$ compounds were obtained for $x=1.5$ and $x=3.0$. Nitrogenation is shown to lead to a sign reversal of the $4f$ and Fe sublattice anisotropy. Mo substitution in $\text{GdCo}_{12-x}\text{Mo}_x$ shows a decreasing negative value of V_{zz} with increasing Mo concentration x . The values $|H_{\text{eff}}|$ in $\text{GdCo}_{12-x}\text{Mo}_x$ increase with increasing Mo concentration. This can be attributed to a different near neighbor Gd and $3d$ -metal contribution to the effective hyperfine field compared to those of $\text{GdFe}_{12-x}\text{Mo}_x$. © 1996 American Institute of Physics. Magnetocrystalline anisotropy is of large importance for permanent magnet materials. Depending on the crystal structure and on the other elements in the compound, there may result a nonsymmetric valence electron distribution. At the site of the rare-earth $4f$ electrons, this charge distribution causes an electric field gradient (EFG). The electrostatic interaction of the spherical $4f$ charge cloud with the EFG gives rise to the crystal field interaction. The $4f$ charge cloud, and its magnetic moment, can be oriented in a preferential direction by the crystal field, and this is the main factor determining the crystalline magnetic anisotropy of the rare-earth sublattice.

By varying the elements which form an isostructural series of intermetallic compounds with gadolinium, the variation of the EFG at the rare-earth nuclear site can be studied in a systematic way using ^{155}Gd Mössbauer spectroscopy. The second-order crystal field parameter A_2^0 is strongly influenced by the variation of the concentration of the substitutional elements, because of hybridization of the rare-earth $5d$ and $6p$ valence electrons with the valence electrons of its neighboring atoms. Gadolinium has a half-filled, spherical $4f$ shell. The $4f$ shell itself thus gives no contribution to the EFG measured at the nucleus, so that this EFG has the same origin as the EFG experienced by the $4f$ electron cloud. Since the $4f$ shell is not involved in the chemical bonding, the EFG at the nuclear site does not depend on the type of rare-earth atoms. Therefore the results of the ^{155}Gd Mössbauer measurements can be used for related rare-earth compounds. In this article we present the results obtained for the

CaCu_5 related compounds, the rhombohedral $\text{Th}_2\text{Zn}_{17}$, and the tetragonal ThMn_{12} compounds, as studied by ^{155}Gd Mössbauer spectroscopy.

The samples were prepared from 99.9% pure elements by arc melting in an argon atmosphere. After arc melting, the samples were wrapped in tantalum foil and vacuum annealed in quartz tubes at $900-1050^\circ\text{C}$ for several weeks and quenched into water. The samples were investigated by powder x-ray diffraction with $\text{Cu } K_\alpha$ radiation on a Philips PW 1800/10 x-ray diffractometer equipped with a single crystal monochromator.

^{155}Gd Mössbauer spectra were measured on a spectrometer described in detail elsewhere,¹ using the 86.5 keV resonance of the ^{155}Gd . The source was neutron-irradiated SmPd_3 , for which we employed samarium enriched to 98% in ^{154}Sm . The measurements were carried out at 4.2 K . The spectra have been analyzed by means of a least square fitting procedure that involved diagonalization of the full nuclear Hamiltonian and use of a transmission integral. The independently refined variables considered in the fitting procedure are the isomer shift (IS), the effective hyperfine field H_{eff} , and the quadrupole splitting (QS). From the latter quantity we obtained the electric field gradient tensor element V_{zz} , via the relation $\text{QS} = \frac{1}{4}eQV_{zz}(\cos^2\theta - 1)$ using the value $Q = 1.30 \times 10^{-28}\text{ m}^2$ given by Tanaka *et al.*² The angle θ between H_{eff} and the c axis was kept at 0° or 90° . The line-width of the absorber and source were constrained for the transmission integral to 0.25 and 0.36 mm s^{-1} , respectively. In some cases where there is some degree of disorder in the compounds due to substitution, the absorber linewidth was kept as an adjustable parameter.

FIG. 1. ^{155}Gd Mössbauer spectrum of the $\text{Gd}_2\text{Fe}_{17}$ compound at 4.2 K. The solid line represents a fit.

Substitution of s and p elements with large atomic radii, such as Al and Ga, for iron in R_2Fe_{17} compounds, has been shown to lead to changes in the crystallographic and magnetic properties. Substantial changes in the magnitude and sign of the Gd valence electron asphericity are expected when Al or Ga preferentially substitutes into specific crystallographic sites.³

The ^{155}Gd Mössbauer spectrum of $\text{Gd}_2\text{Fe}_{17}$ is shown in Fig. 1 and of $\text{Gd}_2\text{Fe}_{17-x}\text{Ga}_x$ are shown in Fig. 2. From the

^aAccording to Ref. 4.

concentration dependence of hyperfine parameters listed in Table I, it follows that the electric field gradient at the nuclear Gd site changes its sign when Al substitution into $\text{Gd}_2\text{Fe}_{17}$ takes place. Therefore, we would expect a similar change in sign for the second-order crystal field parameter A_2^0 in these compounds. Furthermore, using the relationship

$$K_1 = -\frac{3}{2}N\alpha_j \langle r_{4f}^2 \rangle \langle 3J_z^2 - J(J+1) \rangle A_2^0 \quad (1)$$

one would expect that the rare-earth sublattice anisotropy also changes its sign. If $\text{R}_2\text{Fe}_{17-x}\text{Al}_x$ compounds with rare earths having $\alpha_j < 0$ are employed, one would expect a preferred magnetization direction perpendicular to the c axis for small x values, but a direction parallel to the c axis is expected for larger x values. No sign reversal of V_{zz} has been observed in the $\text{Gd}_2\text{Fe}_{17-x}\text{Ga}_x$ compounds (Table I), this is in contrast with previous neutron diffraction studies on $\text{Tb}_2\text{Fe}_{17-x}\text{Ga}_x$ where the easy direction of magnetization changes from planar to uniaxial.¹⁰ This indicates that the rare-earth anisotropy can be large enough to overcome the basal plane oriented iron sublattice anisotropy.

The concentration dependence of hyperfine parameters of the Al and Ga substituted compounds is listed in Table I. In a previous analysis of the hyperfine field in $\text{Gd}_2\text{Fe}_{17}$, it was shown that the total hyperfine field can be decomposed into various contributions⁴ of different sign and magnitude. The contribution of the Fe moments predominates and band structure calculations (see Ref. 12 and references cited therein) confirm an important role of the $6s$ conduction electrons in determining the hyperfine field in $\text{Gd}_2\text{Fe}_{17}$ and other intermetallic compounds. The $6s$ electron polarization resulting from the Fe moments will gradually disappear, which is apparent in the decrease in effective hyperfine field.

The concentration dependence of the isomer shift has been compared with a simple model based on the charge transfer and intra-atomic $s-d$ electron redistribution and volume effects.¹¹ On the basis of this model, one expects that the ultimate value of the isomer shift that would be reached for $x=17$ is 0.52 and 0.64 mm^{-1} for Al and Ga substituted $\text{Gd}_2\text{Fe}_{17}$ compounds, respectively.^{4,6}

FIG. 3. ^{155}Gd Mössbauer spectra of the $\text{GdCo}_{12-x}\text{Mo}_x$ compounds at 4.2 K for several Mo concentrations x . The solid curve through the data points represents a fit.

Ternary compounds with Gd, Fe, or Co having the ThMn_{12} type of structure can be stabilized by substitution of Mo for part of the Fe (Co). Nitrogenation has shown to lead to improved magnetic properties of the $\text{GdFe}_{12-x}\text{Mo}_x$ compounds.⁵ The nitrogen atoms will occupy the interstitial $2b$ site, which is located near the Gd atoms. The ^{155}Gd Mössbauer spectra of $\text{GdCo}_{12-x}\text{Mo}_x$ are shown in Fig. 3. The concentration dependence of the hyperfine parameters of $\text{GdFe}_{12-x}\text{Mo}_x(\text{N}_y)$ and $\text{GdCo}_{12-x}\text{Mo}_x$ are listed in Table II. Nitrogenation is seen to lead to a sign reversal of V_{zz} and the value of V_{zz} exceeds in magnitude the large electric field gradient measured in $\text{R}_2(\text{Fe},\text{Co})_{17}\text{N}_y$ compounds.⁷ The angle θ between the effective hyperfine field and the V_{zz} shows a change from 0° to 90° . The latter feature indicates that there is a nitrogen-induced change in the easy magnetization direction of the Fe sublattice. A decreasing negative value of the electric field gradient V_{zz} can be observed in the $\text{GdCo}_{12-x}\text{Mo}_x$ compounds. The Co sublattice remains uniaxial with increasing Mo concentration. Using Eq. (1) and bearing in mind that A_2^0 has a sign opposite to V_{zz} , one can expect an easy axis type of anisotropy in the

TABLE II. Hyperfine parameters derived from fitting the ^{155}Gd Mössbauer spectra at 4.2 K for various $\text{GdFe}_{12-x}\text{Mo}_x(\text{N}_y)$ and $\text{GdCo}_{12-x}\text{Mo}_x$ compounds.

Compound	V_{zz} (10^{21} V m^{-2})	$\mu_0 H_{\text{eff}} $ (T)	IS (mm s^{-1})	θ (deg)
$\text{GdFe}_{10.5}\text{Mo}_{1.5}$	1.6	9.2	0.21	0
GdFe_9Mo_3	1.9	4.3	0.18	0
$\text{GdFe}_{10.5}\text{Mo}_{1.5}\text{N}_y$	-21.3	7.2	0.35	90
$\text{GdFe}_9\text{Mo}_3\text{N}_y$	-19.9	6.9	0.35	90
$\text{GdCo}_{10.5}\text{Mo}_{1.5}$	-2.1	18.5	0.21	0
$\text{GdCo}_{9.8}\text{Mo}_{2.2}$	-3.1	21.5	0.21	0
$\text{GdCo}_{9.6}\text{Mo}_{2.4}$	-3.2	22.9	0.21	0
GdCo_9Mo_3	-4.5	24.4	0.20	0

$\text{GdFe}_{12-x}\text{Mo}_x\text{N}_y$ and $\text{GdCo}_{12-x}\text{Mo}_x$ compounds when rare earths with $\alpha_j < 0$ are employed.^{8,9}

It can be inferred from the data listed in Table II that the hyperfine fields of the Fe compounds are small and decrease with Mo concentration whereas the hyperfine fields of the Co compounds are comparatively large and increase with Mo concentration. This somewhat surprising behavior can tentatively be explained by strongly different transferred contribution of the Fe and Co moments, bearing in mind that the Fe as well as the Co moments decrease markedly with Mo concentration.

Apparently, the Fe transferred field is positive and dominates the negative core polarization contribution of Gd, leading to a decreasing overall contribution when the former decreases with Mo concentration. The Co contribution, when also positive, is not dominant, when it decreases with increasing Mo concentration the absolute value of the overall hyperfine field increases.

Previously, nuclear magnetic resonance experiments and diffusion calculations have indicated that the distribution of nitrogen atoms in a $Y_2Fe_{17}N_x$ particle with intermediate N content is characterized by a nitrated region and an unnitrated region. In order to *directly* detect this two-region configuration, x-ray diffraction experiments have been carried out on systematically ground nitrogenated samples. Furthermore, x-ray diffraction and ^{89}Y nuclear magnetic resonance on vacuum-annealed samples show that the two-region configuration is stable, and that the nitrogen atoms do not diffuse further into the particle. Thermal conductivity detection measurements indicate that only 5% of the inserted N atoms can be released by vacuum annealing at the nitrogenation temperature. © 1996 American Institute of Physics. [S0021-8979(96)36908-3]

I. INTRODUCTION

It is now well known that nitrogen insertion into rare-earth+Fe intermetallics, such as R_2Fe_{17} , produces materials with significantly improved magnetic properties, namely, the Curie temperature, magnetocrystalline anisotropy, and Fe magnetic moment.^{1,2} A thorough understanding of the nitrogen diffusion process in the host lattice is important for determining the optimal nitrogenation conditions that will result in homogeneous and stable magnetic properties.

Recently, it has been shown that the distribution of nitrogen in a $Y_2Fe_{17}N_x$ particle with intermediate N content is characterized by a nitrated/unnitrated configuration.^{3,4} In a simple case, this can be a shell/core structure. In the nitrated outer shell, all of the *accessible* interstitial sites are occupied by N atoms, and in the inner core, the host lattice is almost devoid of N atoms. These two regions share a thin interface, and the nitrogen atoms in a spherical $Y_2Fe_{17}N_x$ particle have an overall steplike radial distribution. The experimental evidence for this configuration came from ^{89}Y nuclear magnetic resonance (NMR) spectra, which showed that, across the entire range of nitrogen content ($0.6 \leq x \leq 2.8$), there are predominantly two types of Y-N coordination, namely, yttrium with two nitrogen atoms as nearest neighbors (Y+2N), and yttrium with no nitrogen atom as a nearest neighbor (Y+0N).³ This implies that in the nitrated region, two of the three octahedral sites are occupied, and in the unnitrated region, the octahedral sites are empty. The process of nitrogenation results in the growth of the nitrated outer shell at the expense of the unnitrated inner core, with the nitrated region maintaining a Y+2N coordination. The Y+2N coordination for the nitrated region in $Y_2Fe_{17}N_x$ has also been determined from neutron diffraction.⁵ The nitrated/unnitrated configuration was observed in $Nd_2Fe_{17}N_x$ using neutron diffraction,⁶ and in $Pr_2Fe_{17}N_x$ using Mössbauer spectroscopy.⁷ This step-like distribution was studied in several systems, such as $Nd_2Fe_{17}N_{2.3}$, where a sharp interface with thickness of only 1 μm was detected using electron microprobe analysis.⁸

In this article, additional experimental evidence supporting the above nitrated/unnitrated configuration is presented. In order to detect the two regions *directly*, x-ray diffraction

patterns have been obtained from $Y_2Fe_{17}N_x$ samples after successive stages of grinding, and they confirm that the nitrogen distribution is not continuous and the inner core is not nitrated. The stability of the two-region configuration is studied by both x-ray diffraction and ^{89}Y NMR which show essentially no change for a nitrogenated sample upon vacuum annealing. Finally, the number of mobile N atoms is measured directly using thermal conductivity detection (TCD) in an outgassing process, and found to be approximately 5% of the total N content.

II. EXPERIMENTAL APPARATUS AND PROCEDURE

The parent Y_2Fe_{17} ingot, made by arc melting, was homogenized, powdered, and sieved to give particle diameters from 32 to 37 μm . The powder was annealed at 900 °C in an Ar atmosphere for 5 days before nitrogenation, which was performed at 480 °C under an ultrahigh purity (99.999%) N_2 flow. $Y_2Fe_{17}N_x$ samples with different N content ($0.3 \leq x \leq 2.8$) were obtained by varying the nitrogenation time from 0.5 to 18 h. Further vacuum annealing of the $Y_2Fe_{17}N_{1.7}$ sample was performed at 480 °C for 12 h using the same apparatus.

X-ray diffraction patterns were obtained on a Norelco diffractometer using Cu $K\alpha$ radiation. Nitrogen outgassing experiments were carried out on a temperature-programmed desorption apparatus.⁹ A tube containing the $Y_2Fe_{17}N_{2.8}$ sample was subject to a flow of helium gas at a fixed rate. The desorbed nitrogen effluent was detected with a thermal conductivity detector. Spin-echo NMR measurements were made at 4.2 K, in zero external field, using a 120°–120° pulse sequence. The pulsed NMR apparatus, signal coil arrangement, calibration, and data taking procedure have been described in detail elsewhere.¹⁰

III. RESULTS AND ANALYSIS

Figure 1 compares the x-ray diffraction patterns of three powder samples: (a) the parent sample Y_2Fe_{17} ; (b) the “completely” nitrated sample $Y_2Fe_{17}N_{2.8}$; and (c) the intermediate N content sample $Y_2Fe_{17}N_{1.7}$. In Fig. 1(a), a single hexagonal

FIG. 1. X-ray diffraction patterns from (a) the parent sample Y_2Fe_{17} , (b) the "completely" nitrided sample $Y_2Fe_{17}N_{2.8}$, and (c) an intermediate N content sample $Y_2Fe_{17}N_{1.7}$. Two sets of Bragg peaks are visible in the reground $Y_2Fe_{17}N_{1.7}$ samples, showing the nitrided outer shell and the unnitrided inner core. Also, there is no significant structural differences between the as-nitrogenated and vacuum-annealed samples of $Y_2Fe_{17}N_{1.7}$.

Y_2Fe_{17} phase with no bcc α -Fe is identified for the parent sample. For the $Y_2Fe_{17}N_{2.8}$ sample [Fig. 1(b)], the same structure as the parent sample is identified except that all of the Bragg peaks are shifted to lower angles due to volume expansion. Also, a small amount of α -Fe precipitation is present. In Fig. 1(c), the Bragg peaks from the as-nitrogenated $Y_2Fe_{17}N_{1.7}$ sample are *not* located, commensurate with its intermediate N content, between the diffraction peaks in Figs. 1(a) and 1(b). Rather, they are located essentially at the same angles as those in Fig. 1(b), indicating a near complete nitrogenation of the surface region of the particle since the penetration depth for x rays in $Y_2Fe_{17}N_x$ is less than 5 μm . In order to expose the interior of the particles to the x rays, the $Y_2Fe_{17}N_{1.7}$ sample was ground in stages to obtain three samples with particle diameters of 25–32, 20–25, and <20 μm . As shown in Fig. 1(c), the three ground $Y_2Fe_{17}N_{1.7}$ samples have an extra set of Bragg peaks that correspond to the unnitrided parent sample Y_2Fe_{17} shown in Fig. 1(a). Furthermore, the smaller the particle size, the larger the peaks in the second set, showing directly more of the unnitrided inner core. A careful inspection of the x-ray patterns shows that the 2θ value of a peak in the unnitrided phase for a sample with intermediate N content is a little smaller than that for the parent Y_2Fe_{17} sample, and the 2θ value of a peak in the nitrided phase for a sample with intermediate N content is a little larger than that for the completely nitrided sample. The result can be explained by lattice

FIG. 2. ^{89}Y NMR spectra from as-nitrogenated and vacuum-annealed samples of $Y_2Fe_{17}N_{1.7}$, showing no significant structural changes after vacuum annealing at the nitrogenation temperature.

strain since the two phases coexist in the sample particle. Lattice strain will result in the phase with smaller lattice constants being stretched, and the phase with large lattice constants being compressed.

As discussed below, the reason for the formation of such a two-region distribution is a strong chemical bond between a nitrogen atom in an interstitial octahedral site and the surrounding environment in the lattice. If there is such a trapping of the N atoms at the nitrogenation temperature (480 $^{\circ}C$), then the distribution should be stable at the same temperature. The nitrogenated samples have been vacuum annealed, and x-ray diffraction and ^{89}Y NMR have been used to detect any changes in the N distribution. Both the x-ray diffraction pattern [Fig. 1(c)] and the NMR spectrum (Fig. 2) of the vacuum-annealed $Y_2Fe_{17}N_{1.7}$ sample remain unchanged from the as-nitrogenated sample. These experiments verify the stability of the two-region distribution, and therefore, the strong N-lattice bonding.

Finally, the number of mobile N atoms in the $Y_2Fe_{17}N_{2.8}$ sample was analyzed quantitatively in an outgassing experiment using thermal conductivity detection (TCD). The TCD signal voltage which was recorded as the temperature of the sample increased showed three peaks, each corresponding to an effluence of N atoms from the sample. A first peak near 120 $^{\circ}C$ was attributed to those N atoms adsorbed on the surface, which accounted for about 1% of the total N content. A second peak near 380 $^{\circ}C$ was attributed to the outgassing of the mobile N atoms inside the sample. Finally, a third peak, or sudden increase in the TCD signal, above 600 $^{\circ}C$ was attributed to nitrogen release during the phase decomposition into YN and α -Fe. In order to obtain a reasonable estimate for the amount of nitrogen release associated with the second peak, the TCD experiment was repeated with the temperature scan programmed to stop rising at 460 $^{\circ}C$ (above the second peak but below the temperature of phase decomposition). During a 15 min period at a constant temperature of 460 $^{\circ}C$, the mobile N atoms were completely evacuated from the

FIG. 3. Schematic diagram showing the nitrogen distribution in a spherical particle. The horizontal scale represents the radial direction across the particle, and the vertical scale represents the N concentration in nitrogen atoms per unit cell in $Y_2Fe_{17}N_x$.

sample. Integration of the second peak and comparison with a standard calibration curve showed that about 5% of the total N content can be released. If none of N atoms were trapped in the interstitial sites, then during the vacuum-annealing process the N atoms would either diffuse further towards the interior of the particle or leave the particle through its surface. The first possibility would have caused changes in the x-ray diffraction pattern and NMR spectrum, whereas the second possibility would have been detected in the outgassing experiment. The experiments rule out both of these scenarios for the majority of N atoms in the $Y_2Fe_{17}N_x$ system.

IV. DISCUSSION AND CONCLUSIONS

To date, two different models have been proposed for describing the nitrogen distribution in $R_2Fe_{17}N_x$. One is based on a simple diffusion mechanism that results in a continuous solid solution distribution (CSSD) with a smooth concentration gradient.^{11,12} The second model considers a chemical reaction diffusion process with two types of N atoms that leads to a steplike radial distribution with a nitrided shell and an unnitrided core (see Fig. 3).⁴ One type of nitrogen atom is characterized by its immobility once the atom enters an accessible octahedral site (trapped type, or *t*-type), and the other has a relatively large diffusion constant (free-type, or *f*-type). It is reasonable to believe that the *f*-type atoms are located in the tetrahedral interstitial sites as reported in a previous ¹⁴N NMR study on both hexagonal and rhombohedral $Y_2Fe_{17}N_x$.¹³ The *t*-type atoms are immobilized because of a strong chemical bond with the lattice. The *f*-type atoms can diffuse easily only in the region where all the "traps" are filled, otherwise an *f*-type atom would fall

into an octahedral site and convert itself into a *t*-type atom. In the outer shell, therefore, all accessible interstitial octahedral sites are occupied by *t*-type N atoms, and a relatively small number of *f*-type atoms "ride" on the nitrided region and diffuse towards the interface where octahedral interstitial sites are available. Once an *f*-type atom reaches the interface, it is immediately trapped and converts to a *t*-type atom, leaving a sharp boundary between the nitrided outer region and an unnitrided inner one. Through this process, the interface advances towards the center of the particle, and the nitrogen content in the sample increases with nitrogenation time. If the nitrogenation is terminated, either by removing the nitrogen gas source or by reducing the temperature, then the interface ceases to move and the steplike distribution is preserved. In the case that the trapping has a relatively deep potential well, this two-region configuration is stable. The chemical reaction diffusion process with two types of N atoms described above has been treated theoretically in a previous work which calculates the radial dependence of the nitrogen distribution (see Fig. 3).⁴ In addition, this model explains the abnormally small (apparent) diffusion frequency factor which characterizes these newly developed R_2Fe_{17} nitrides.⁴

Finally, the "nominal" nitrogen content is usually obtained by weighing the sample before and after nitrogenation; consequently, there are errors as not all the N atoms absorbed into the entire sample are coordinated with the Y atoms in the 2:17 phase. Also some of the weight gain of the sample may be due to factors other than N absorption. This may offer an explanation as to why different studies have reported different N content values, while the corresponding lattice expansion and magnetic properties were not so different. A detailed analysis of the difference between the N content measured gravimetrically and the Y-N coordination measured by NMR has been published previously.¹⁴

The nuclear magnetic resonance spin-echo spectra of ^{89}Y and ^{147}Sm for Y_2Fe_{17} , $\text{Y}_2\text{Fe}_{17}\text{C}_{0.4}$, $\text{Y}_2\text{Fe}_{17}\text{C}_{1.5}$, $\text{Y}_2\text{Fe}_{17}\text{N}_{2.5}$, $\text{Y}_2\text{Fe}_{17}\text{CN}_{1.5}$, $\text{Y}_2\text{Fe}_{17}\text{H}_{1.6}$, and $\text{Sm}_2\text{Fe}_{17}$ have been measured at pressures up to 10 kbar at 4.2 K. A reduction of the magnitude of the valence electron polarization contribution to the effective field B_e at Y and Sm sites with pressure is observed. The effect is strongly related to the nearest neighbor environment of the site. A significant reduction of $\partial B/\partial p$ is observed for the sites with nitrogen neighbors. Carbon increases (decreases) $\partial B/\partial p$ in the rhombohedral (hexagonal) structure of the compound. A decrease of the lattice electric field gradient at the Sm site in $\text{Sm}_2\text{Fe}_{17}$ with pressure is observed. A corresponding decrease of the crystal electric field coefficient A_2^0 at the Sm site with pressure of 0.7% per kbar is derived, indicating an anisotropic compressibility of the material. © 1996 American Institute of Physics. I. INTRODUCTION

The compounds $\text{RE}_2\text{Fe}_{17}\text{A}_x$ where RE is a rare earth or yttrium and A is a light interstitial element belong to the family of the recently discovered interstitially modified materials for permanent magnet applications.^{1,2} An uptake of carbon or nitrogen by these materials dramatically raises their magnetic ordering temperatures and induces a strong uniaxial anisotropy in the $\text{Sm}_2\text{Fe}_{17}$ nitride and carbide making them eligible for applications. In our recent nuclear magnetic resonance (NMR) study of these materials, information on the site distribution of interstitial atoms and their influence on the effective (hyperfine) magnetic fields B_e and electric field gradients (EFG) measured at nuclei was obtained.^{3,4} In the present study we report high pressure NMR measurements of the individual site yttrium and samarium hyperfine fields as well as the Sm electric field gradient in these materials. The pressure dependence of these quantities reflects the individual site contributions to the magnetoelastic properties of the materials. In order to compare the influence of different interstitial atoms, samples of Y_2Fe_{17} , $\text{Y}_2\text{Fe}_{17}\text{C}_{0.4}$, $\text{Y}_2\text{Fe}_{17}\text{C}_{1.5}$, $\text{Y}_2\text{Fe}_{17}\text{N}_{2.5}$, $\text{Y}_2\text{Fe}_{17}\text{CN}_{1.5}$, $\text{Y}_2\text{Fe}_{17}\text{H}_{1.6}$, and $\text{Sm}_2\text{Fe}_{17}$ were measured.

The host compounds crystallize in the hexagonal structure for Y and in the rhombohedral structure for Sm. The carbide $\text{Y}_2\text{Fe}_{17}\text{C}_{0.4}$ and the nitride are hexagonal, whereas $\text{Y}_2\text{Fe}_{17}\text{C}_{1.5}$ and the carbonitride $\text{Y}_2\text{Fe}_{17}\text{CN}_{1.5}$ and $\text{Sm}_2\text{Fe}_{17}$ are rhombohedral. RE elements occupy a single site (6c) in the rhombohedral and two sites (2b,2d) in the hexagonal structure. The 2b site has 18 Fe and 2 RE atoms as the nearest neighbors (NN), the 2d has 20 Fe and 0 RE neighbors and for the 6c the numbers of neighbors are 19 Fe and 1 RE, respectively. Neutron diffraction experiments have shown that the C atoms randomly occupy the interstitial positions 6h (9e).⁵ Hydrogen atoms for hydrogen content $x < 3$

per formula unit mostly locate at 6h (9e) sites.⁶ Nitrogen locates almost entirely at 6h (9e) interstitial positions,⁷ but recently a discussion about its possible location at the 18g (12i) sites has aroused considerable interest.⁸ The number of 9e (6h) NN sites to a RE site is 3.

Pressure measurements were carried out using a Be-Cu pressure cell with an untuned rf coil as the NMR probe head. The cell, filled with petroleum spirit, was pressurized to about 12 kbar and locked at room temperature and then cooled down to 4.2 K. The maximum pressure obtained at 4.2 K was about 10 kbar which was measured by a semiconductor pressure transducer. The ^{89}Y and ^{147}Sm NMR spin-echo spectra were taken at 4.2 K, using an automated, computer controlled spin-echo spectrometer.⁹ A sequence of two constant amplitude radio frequency pulses of 0.2 and 0.4 μs , spaced at 15 μs was applied. Powder samples, the same as those used in Refs. 3 and 4 were measured. The spectra taken at ambient pressure are shown in Figs. 1 and 2.

II. RESULTS AND DISCUSSION

A. $\text{Y}_2\text{Fe}_{17}\text{A}_x$

The NMR spectra obtained at ambient pressure, Fig. 2, are very similar to those reported in Ref. 3. The spectrum for Y_2Fe_{17} consists of a single, asymmetric ^{89}Y line ($I=1/2$ —no quadrupole splitting) with a shoulder at its high frequency side, reflecting the presence of the two Y sites in the compound. For the carbides $\text{Y}_2\text{Fe}_{17}\text{C}_{0.4}$, $\text{Y}_2\text{Fe}_{17}\text{C}_{1.5}$, and the nitride three additional lines appear indicating a strong effect of C and N neighbors on the Y valence electron polarization. Following Ref. 3 they are assigned to the Y sites with one, two, and three C (N) atoms, respectively. A single ^{89}Y line is observed for the hydride indicating the lack of a local influ-

FIG. 1. The ^{89}Y NMR spin-echo spectra of the $\text{Y}_2\text{Fe}_{17}\text{A}_x$ ($\text{A}=\text{N}, \text{C}, \text{H}$) compounds at 4.2 K and ambient pressure.

ence of hydrogen on Y electronic structure. The line has a slightly larger width and is shifted to a lower frequency with respect to that of Y_2Fe_{17} .

The ^{89}Y spectra obtained at high pressure show shifts of the resonance lines towards lower frequencies, which corresponds to a decrease in magnitude of B_e at Y nuclei with pressure. The values of B_e corresponding to the frequencies of the Y resonance lines were obtained using the conversion factor of -0.5647 T/MHz . The values of $\partial B_e/\partial p$ and $(1/B_e)\partial B_e/\partial p$ corresponding to the Y sites with zero, one, and two C (N) neighboring atoms are listed in Table I. The data for three C (N) lines bear large errors and they are not shown here. Since the changes of B_e up to maximum pres-

sure of 10 kbar were found to be small ($<0.5\%$), we assume that B_e is a linear function of pressure over this range.

The value of $(1/B_e)\partial B_e/\partial p$ obtained for Y_2Fe_{17} amounts to $-24 \times 10^{-4}/\text{kbar}$, close to that of $-29 \times 10^{-4}/\text{kbar}$ derived from theoretical calculations.¹⁰ The present value is 30% larger in magnitude than was reported previously.¹¹ The discrepancy can be attributed to the fact that Y_2Fe_{17} samples which show hexagonal structure, also contain stacking faults corresponding to the rhombohedral 6c sites. The derived value of $(1/B_e)\partial B_e/\partial p$ therefore corresponds to an average over the three environments which vary their relative population in a way sensitively dependent on sample preparation conditions.

Comparing the values of $(1/B_e)\partial B_e/\partial p$ of the same sites [e.g., hexagonal zero C (N)] in the carbides, the nitride and the carbonitride we see the same pressure sensitivity irrespective of the material in which they appear, i.e., their local environment predominantly determines their pressure behavior. The rhombohedral zero C (N) sites have a pressure sensitivity 40% lower than the hexagonal ones. Hexagonal sites with carbon neighbors slightly decrease their pressure sensitivity with increasing number of C neighbors, whereas an opposite effect is observed for the rhombohedral sites. Nitrogen neighbors reduce considerably pressure effects in both structures. For the hydride a slightly larger pressure derivative from that in the host compound is found. It corresponds to an average over the Y sites with zero, one, two, and three H neighbors which are not resolved in the spectrum.

The effective field induction B_e at Y nuclei originates mainly from the polarization of Y 5s-like electrons by neighboring magnetic Fe atoms, contributing to B_e via direct contact interaction. A smaller contribution originates from the 4d electrons bearing a small magnetic moment and contributing to B_e via core electron polarization. These contributions are of opposite sign. The contribution from the valence s-electron polarization is often called the transferred hyperfine field (THFF) and is antiparallel to the direction of neighboring Fe moments. From theoretical calculations for Y_2Fe_{17}

using the experimental lattice constants and for the expanded lattice¹² one can see that both contributions decrease in magnitude with applied pressure, reflecting a decrease of Fe magnetic moments. The THFF contribution changes more rapidly under pressure and thus determines the sign of the total change. The total B_e and the relative ratio of both contributions, however, change with nitriding or carbiding. The ratio of THFF to the $4d$ contribution for $Y_2Fe_{17}C_3$ is smaller than for Y_2Fe_{17} whereas for $Y_2Fe_{17}N_3$ it is larger. Assuming a similar pressure behavior of both contributions at the sites with C (N) neighbors to that in Y_2Fe_{17} one would expect a larger pressure sensitivity for the nitride. Surprisingly, nitrogen neighbors cause a dramatic reduction of $(1/B_e)\partial B_e/\partial p$ which is especially large for the two N sites. Thus, a different mechanism of the effect has to be considered and we attribute it to different compressibilities of the local environments of the sites with C or N neighbors.

B. Sm_2Fe_{17}

The ^{147}Sm spectrum obtained at ambient and high pressure was found to be similar to that reported in Ref. 13. It consisted of a single quadrupole septet corresponding to the single Sm crystallographic site $6c$. The change of B_e with pressure was derived from the central line frequency shift using the conversion factor of 0.5689 T/MHz. The value of quadrupole splitting derived from the line separations at ambient pressure ν_q is 12.017 MHz, and it decreases with pressure by 0.004 MHz/kbar. The corresponding change of the electric field gradient (EFG) component along the hyperfine field V_{ii} was derived using the conversion factor of -21.85×10^{20} V/m² MHz. The change of V_{ii} at pressure amounts to 0.084×10^{20} V/m² kbar. Since the change at the maximum pressure of 7.5 kbar is found to be small ($<0.3\%$), we assume that V_{ii} is a linear function of pressure over this range.

The effective field on Sm nuclei is dominated by a huge contribution from the orbital current of $4f$ electrons. As the coupling between the Sm and Fe spins is antiparallel and the Sm spin and orbital moments are also coupled in antiparallel, the contribution is positive with respect to the local magnetization direction determined by Fe moments. A much smaller contribution to B_e arising from polarization of Sm valence electrons by the Fe magnetic moments is of opposite sign. A similar pressure derivative $\partial B_e/\partial p$ of Y and Sm HFF in Y_2Fe_{17} and Sm_2Fe_{17} indicates that the effect of pressure is related to the behavior of valence electrons. In view of the above analysis an increase of B_e with pressure corresponds to a decrease of valence electron contribution and is consistent with the effect observed for Y_2Fe_{17} .

The NMR signal for Sm_2Fe_{17} corresponds to the local magnetization direction in the basal c plane.¹³ Thus, B_e has its direction in the c plane and the EFG value obtained from quadrupole splitting corresponds to this plane. The EFG is a sum of the contributions from $4f$ electrons $V_{zz}(4f)$ and from the nonspherical distribution of the $5d$ and $6p$ electrons of the parent atom. This nonspherical distribution originates from interaction with neighboring ions in the lattice.¹⁴ The $4f$ contribution lies in the Sm moment direction,⁴ whereas

the latter contribution, called the lattice EFG, is coupled to the crystal lattice. The lattice EFG tensor for the $6c$ site is axially symmetric along the c axis.

We attribute the decrease of magnitude of the EFG under pressure to a change of magnitude of the lattice EFG. The possibility of a change of $4f$ contribution is rather unlikely, since it would be accompanied by a corresponding decrease of the orbital contribution to B_e and thus a decrease of B_e , which is not the case. Another possibility is that the change of V_{ii} could be caused by a change of B_e direction possibly related to a tilting of Sm moments towards the c axis. This is also unlikely, as it would also imply a decrease of B_e .⁴ The change of V_{ii} related to the lattice EFG component in the basal c plane, $[1/V_{ii}(\text{latt})]\partial V_{ii}(\text{latt})/\partial p$, amounts to $7 \times 10^{-3}/\text{kbar}$ from a V_{ii} value of -13×10^{20} V m⁻². This change corresponds to a decrease in magnitude as compared to the value at ambient pressure. A simple point charge model, assuming isotropic compressibility, predicts an increase of magnitude of $[1/V_{ii}(\text{latt})]\partial V_{ii}(\text{latt})/\partial p$.

The lattice EFG measured at RE nuclei in these materials is roughly proportional to the EFG exerted by the $4f$ electron shell quadrupole moment.¹⁴ Thus, assuming a proportionality between lattice EFG and the crystal electric field (CEF) coefficient A_2^0 we arrive at a relative change of A_2^0 with pressure of $-0.7\%/kbar$. The negative sign corresponds to a decrease of A_2^0 with increasing pressure. For isotropic compressibility one would expect an increase of A_2^0 . Thus, the result indicates a large anisotropy in the compressibility of the material.

Band theoretical investigation of the Curie temperatures of modified R_2Fe_{17} -based intermetallic compounds

W. Y. Ching and Ming-Zhu Huang

Department of Physics, University of Missouri–Kansas City, Kansas City, Missouri 64110

The Curie temperatures of several Nd_2Fe_{17} -based intermetallic compounds are calculated based on the spin-fluctuation model of Mohn and Wohlfarth and the band structure results calculated using the self-consistent orthogonalized linear combinations of the atomic orbitals method in the local spin density approximation. It is shown that the calculated T_c can qualitatively account for the observed T_c enhancement in this class of modified compounds by interstitial doping of N or C, or by elemental substitution of Fe by Si, Al or Ga. A simple explanation of T_c enhancement based purely on the magnetovolume effect is not justified. It is also shown that neither the Stoner–Curie temperature nor the characteristic spin-fluctuation temperature is adequate to explain the experimentally observed T_c enhancement in these compounds. © 1996 American Institute of Physics. [S0021-8979(96)49408-8]

In recent years, research on hard magnets has shifted from $R_2Fe_{14}B$ (2-14-1) phase to the R_2Fe_{17} (2-17) phase (R = rare earth) of intermetallic compounds. This is because the latter has a greater Fe content and the possibility of increasing Curie temperature T_c by interstitial doping of N or C,^{1–5} or by elemental substitution of Fe by other metal or metalloid elements such as Al, Si, and Ga.^{6–12} The rationale is that T_c can be increased by expanding the lattice thereby increasing the Fe–Fe separation. The change in the Fe–Fe exchange interaction coupled with local moment increase result in the enhancement of T_c . However, it was soon realized that in the case of Si substitution in Nd_2Fe_{17} , T_c increases even when the lattice contracts.⁹ Thus magnetovolume effects can account at most only a part of the observed T_c enhancement. It is highly desirable if theoretical calculations can shed some light on the underlying mechanism for T_c enhancement in these promising hard magnets. Quantitative prediction of transition temperatures in magnetic materials is an outstanding problem in the theory of magnetism.¹³ Ferromagnetic phase transition involves complicated many particle and spin interactions, and even for the pure 3d transition metal crystals, quantitative prediction of T_c has not been fully successful. The simplest approach using the spin-polarized band results appears to be the theory of Gunnarsson¹⁴ based on the Stoner model for itinerant electron magnetism¹⁵ in which T_c^s , the Stoner–Curie temperature is identified as the solution of the equation:

$$I \int_{-\infty}^{+\infty} \frac{\partial f(E, T)}{\partial E} N(E) dE + 1 = 0, \quad (1)$$

where I is the Stoner parameter generally given by $I = \Delta E / M_0$, $N(E)$ is the density of states (DOS) per atom per spin and $f(E, T)$ is the Fermi function. ΔE is the exchange splitting energy and M_0 is the equilibrium magnetic moment at $T = 0$. Gunnarsson estimated the T_c for Fe, Co, and Ni using expression (1) and found the T_c to be a factor of 3 to 5 larger than the measured T_c .¹⁴ It was soon realized that a correct theory should include the effect of spin fluctuation.¹⁶ Mohn and Wohlfarth (MW)¹⁷ have derived an expression for the characteristic temperature T_{sf} describing the effect of spin fluctuation in the long wavelength limit given by $T_{sf} = [M_0]^2 / 10 k_B \chi_0$, where k_B is the Boltzmann's constant

and χ_0 is the exchange-enhanced susceptibility at equilibrium:

$$\chi_0^{-1} = \frac{1}{4\mu_B^2} \left(\frac{1}{N^\uparrow(E_F)} + \frac{1}{N^\downarrow(E_F)} \right) - \frac{I}{2\mu_B^2}, \quad (2)$$

where $N^\uparrow(E_F)$ and $N^\downarrow(E_F)$ are the DOS of the majority (spin-up) and the minority (spin-down) spin bands at the Fermi level (E_F), respectively. The Curie temperature T_c is obtained from the quadratic equation involving both T_{sf} and T_c^s

$$\frac{T_c^2}{(T_c^s)^2} + \frac{T_c}{T_{sf}} = 1. \quad (3)$$

In the limit of pure spin fluctuation, $T_c = T_{sf}$ and on the opposite limit of pure Stoner model with no spin fluctuation, $T_c = T_c^s$. Mohn and Wohlfarth obtained T_c for Fe, Co, and Ni in good agreement with the experimental data.¹⁷ In addition, the T_c obtained for several Y-based intermetallic Fe and Co compounds using the band structures calculated by others were also in reasonable agreement with experimental data.

We have recently calculated the spin-polarized band structures of Nd_2Fe_{17} and Y_2Fe_{17} crystals using the first-principles orthogonalized linear combinations of the atomic orbitals (OLCAO) method,^{18,19} and also their modified forms with interstitial doping of C or N¹⁹ or by replacing Fe on selected sites by Al, Si, or Ga.^{20,21} It is therefore instructive to see if the variation of T_c in these compounds can be accounted for by the spin-fluctuation model of MW. Such calculations for T_c can be considered first-principles since the only experimental information used is the crystal structure of the compound. However, before we present the results, it should be pointed out that such investigation may not be very quantitative for the following reasons. First, calculations for the modified Nd_2Fe_{17} compounds have a much greater degree of uncertainty than in pure transition metals. The calculations were carried out on the rhombohedral unit cell ($R\bar{3}m$, 19 atoms/unit cell). Ideally, a supercell approach with statistical distribution for the modified sites should be used. Second, the effect of the presence of Nd is treated in the context of localized moment theory and thus plays no role in the present theory for T_c which is based on itinerant magnetism. However, the presence of Nd does change the

TABLE I. Calculated magnetic properties of some $\text{Nd}_2\text{Fe}_{17}$ -based compounds. ΔV is the % change of the cell volume relative to $\text{Nd}_2\text{Fe}_{17}$. $T_c(\text{expt.})$ and $T_c(\text{cal.})$ are the experimental and the calculated Curie temperature in K. T_{sf} and T_s^c are the spin-fluctuation and the Stoner–Curie temperatures respectively in K. $N^\uparrow(E_F)$ and $N^\downarrow(E_F)$ are the density of states at the Fermi level for spin-up and spin-down bands, respectively, in the unit of states/spin-formula unit of Fe sublattice. ΔE is the calculated exchange splitting in eV. $M(\mu_B)$ is the calculated total moment for the Fe sublattice. I is the Stoner parameter.

electronic structure, and hence the calculated T_c due to the slight hybridization of the Nd 4f orbitals with the conduction electrons. Third, the presence of the nonmagnetic elements in system is not anticipated in the original theory for T_c^s and T_{sf} . In the present calculations, only the moments and the DOS of the Fe sublattice are used. It is not clear if this is the most valid choice. Electronic structure results show the nonmagnetic atoms are slightly polarized and order antiferro-

magnetically with the Fe lattice.^{20,21} Fourth, the experimental values for T_c and also the crystal parameters used in the calculations are uncertain to a large extent. Most of these materials are susceptible to partial disorder and nonstoichiometry. In the case of elemental substitutions, the actual site occupation of the substituted sample may involve several Fe sites with different probability of occupation. Also, the calculations do not consider any lattice relaxation effects which

FIG. 1. Calculated and measured T_c for some $\text{Nd}_2\text{Fe}_{17}$ based compounds. There are uncertainties in the experimental T_c values. See the text for explanation. % numbers in the parentheses indicate the change in the crystal volume.

may occur. In spite of all these uncertainties, we believe a systematic calculation on as many systems as possible and a careful interpretation of the calculated results can provide some understanding on the nature of T_c enhancement in the $\text{Nd}_2\text{Fe}_{17}$ -based hard magnets.

We chose eight systems where the experimentally measured T_c are either available or can be reasonably extrapolated. They are: (a) $\text{Nd}_2\text{Fe}_{17}$, (b) $\text{Nd}_2\text{Fe}_{16}\text{Si}_1$, (c) $\text{Nd}_2\text{Fe}_{15}\text{Si}_2$, (d) $\text{Nd}_2\text{Fe}_{15}\text{Si}_3$, (e) $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$, (f) $\text{Nd}_2\text{Fe}_{15}\text{Al}_2$, (g) $\text{Nd}_2\text{Fe}_{17}\text{N}_3$, and (h) $\text{Nd}_2\text{Fe}_{17}\text{C}_3$. We used the $\text{Nd}_2\text{Fe}_{17}$ systems as the reference²² and investigate the relative changes in T_c under various substitutions. Only the average Fe moments are used and the slight negative polarizations of the other atoms are ignored. The exchange splitting energy is defined as the separation between the center of gravities of the projected spin-up and spin-down Fe partial DOS.

Our calculated results for the eight crystals are summarized in Table I. It can be seen that the calculated T_c are generally higher than the experimental values. The largest deviation is in the case of $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$. This is more clearly shown in Fig. 1. The experimental data for $\text{Nd}_2\text{Fe}_{17}\text{N}_3$ and $\text{Nd}_2\text{Fe}_{17}\text{C}_3$ are actually taken from the measurements on $\text{Nd}_2\text{Fe}_{17}\text{N}_x$ ($x=2.3-2.7$),²⁻⁴ and $\text{Nd}_2\text{Fe}_{17}\text{C}_2$,⁵ so the more appropriate values for experimental T_c corresponding to the crystals in the calculation should be somewhat higher. Also shown in Fig. 1 are the percentage increase (decrease) in the crystal volume compared to the reference crystal $\text{Nd}_2\text{Fe}_{17}$. The volumes are calculated according to the structural measurements for each compound, and are the same ones that enter into the calculation. As can be seen, $\text{Nd}_2\text{Fe}_{16}\text{Si}_1$, $\text{Nd}_2\text{Fe}_{15}\text{Si}_2$, and $\text{Nd}_2\text{Fe}_{15}\text{Si}_3$ actually have slight reduction in volume of about 0.6%, 1.0%, and 1.2%, respectively. All three crystals show relative increase in T_c over $\text{Nd}_2\text{Fe}_{17}$. Thus the qualitative estimates for T_c obtained from the present calculation is in fair agreement with experiments and do not support the notion that magnetovolume effect alone can explain the T_c enhancement in the R_2Fe_{17} -based hard magnets. From Table I, it is also observed that the Stoner parameters for seven of the eight crystals are all very close, being in the range of 1.0–1.08. For $\text{Nd}_2\text{Fe}_{17}\text{N}_3$, it is a bit higher at 1.13 because of a smaller value of the average Fe moment. This is probably due to the stronger negative polarization of the N atoms which reduces the moments of the nearby Fe atoms.

One interesting observation of the results from Table I is that both T_c^s and T_{sf} are larger than T_c . This is not surprising since this was also the case with the transition metals and Y-based Fe compounds.¹⁰ However, our calculations show that T_{sf} can be larger or smaller than T_c^s and there is really no obvious trend in correlation with the volume expansion or contraction. This is due to the fact that the DOS at the Fermi level are very much system dependent. For $\text{Nd}_2\text{Fe}_{17}$, $N(E_F)$ for the majority spin band is greater than the $N(E_F)$ for the minority spin band. The order is reversed in six of the seven doped or substituted systems with the largest shift found in $\text{Nd}_2\text{Fe}_{15}\text{Si}_3$ and $\text{Nd}_2\text{Fe}_{15}\text{Ga}_2$. This is mainly due to a large reduction in the majority spin bands DOS by a factor of more than two, while the change in the minority spin band is much smaller. This sensitive dependence of the $N(E_F)$ can be

traced to the changes in the electronic structure due to crystal modifications at various Fe sites,^{20,21} and obviously significantly affects χ_0 , and hence the final T_c . Since the calculated T_c and T_{sf} do not exhibit the same relative change, the use of spin-fluctuation temperature T_{sf} as an estimation for T_c may not be totally justified.²³

In conclusion, we have estimated the Curie temperatures of several $\text{Nd}_2\text{Fe}_{17}$ -based hard magnets using the electronic structure results calculated according to the local spin-density approximation and the spin-fluctuation model of Mohn and Wohlfarth. Our results indicate that the MW model can provide a qualitative account for the T_c variation and the simple argument based on magnetovolume effect is inadequate. However, accurate determination of T_c from first principles for these complicated intermetallic compounds is quite difficult because T_c is related not only to the total Fe moments, the Stoner parameter and the density of states at the Fermi level, but also to the subtle interplay among these physical parameters. Additional theoretical work and more precise calculations are clearly needed to further advance the understanding of the magnetic properties of the rare-earth Fe-based permanent magnets.

Metastable RFe_7 compounds (R =rare earths) and their nitrides with $TbCu_7$ structure

O. Mao, J. Yang, Z. Altounian, and J. O. Ström-Olsen

Center for the Physics of Materials, Department of Physics, McGill University, Montréal, Québec H3A 2T8, Canada

RFe_7 compounds with the $TbCu_7$ structure have been synthesized by annealing of mechanically alloyed powders. The lattice constants a and c decrease with increasing atomic number of the rare earths except for Ce which has a different valence state. Introduction of nitrogen interstitial atoms into the structure results in a $\sim 6.0\%$ volume expansion. In addition, nitriding gives rise to a dramatic enhancement of the magnetic properties of the compounds. Curie temperatures are increased by $\sim 300^\circ\text{C}$ upon nitriding. RFe_7 nitrides with $R=\text{Sm, Tb, Dy, and Ho}$ have high coercivities. A substantial enhancement in the magnetic remanence for the RFe_7 nitrides with $R=\text{Tb, Dy, and Ho}$ is attributed to the magnetic exchange coupling between grains of nanocrystalline structure in the powders. © 1996 American Institute of Physics. [S0021-8979(96)37108-4]

I. INTRODUCTION

In the preparation of $\text{Sm}_2\text{Fe}_{17}$ -type compounds, a metastable Sm-Fe phase with $TbCu_7$ structure commonly appears in samples prepared by nonequilibrium processes, such as rapid solidification,¹ mechanical alloying (MA),² and film growth. Similar to other $R\text{-T}$ compounds (T =transition metals), the $TbCu_7$ structure can be derived from RT_5 (CaCu_5 structure), by replacing an appropriate amount of R atoms with pairs of T dumbbells. In the $TbCu_7$ structure this substitution takes place randomly. Therefore, the $TbCu_7$ structure can also be considered as a derivative of the 2:17 structure without long range ordering and this structure is sometimes described as a disordered 2:17 structure or even as 2:17 by some authors. To clarify the confusion between the RFe_7 - and the R_2Fe_{17} -type structures, we report the synthesis of the RFe_7 -type compounds and their nitrides by MA with subsequent annealing, and a systematic study of the structural and magnetic properties of these compounds.

II. EXPERIMENTAL TECHNIQUES

The RFe_7 alloy ingots were prepared by melting the appropriate amounts of Fe (purity better than 99.99 wt. %) and rare earth (99.9 wt. %) in a cold crucible induction furnace. The as-made ingot was crushed to small pieces of size less than 1 mm and, together with two hardened steel balls of diameter 12.7 mm, loaded to a hardened steel vial and sealed. Mechanical alloying (MA) was carried out in a high energy SPEX-8000 Mixer/Mill for 20 h. Ball-to-material ratio was 10:1. The crushing, weighing, loading, sealing, as well as subsequent handling procedures were performed in a specially designed glove box with oxygen and humidity levels of less than 1 ppm. For annealing treatments, the samples were sealed in a quartz tube under Ar. Annealing time was kept at 30 min. Nitriding was carried out by holding the powders at 450°C for 10 h under 1 atm of nitrogen pressure. X-ray diffraction (XRD) was performed in an automated Nicolet-Stöe powder diffractometer with graphite monochromated $\text{Cu } K\alpha$ radiation. Curie temperatures, T_c 's, were measured by thermomagnetometry using a Perkin-Elmer thermogravimetric analyzer (TGA-7) in a small magnetic

field gradient (TGAM). Vibrating sample magnetometry (VSM) with 1.6 T maximum field were used to measure the hysteresis loops and the saturation magnetizations at room temperature.

III. RESULTS AND DISCUSSION

A. Formation and the structure of the RFe_7 compounds

After MA, the as-milled powder contained a mixture of metastable phases including a large amount of nanocrystalline $\alpha\text{-Fe}$ of grain size ~ 10 nm estimated through the width of the related Bragg peaks. For RFe_7 with $R=\text{Ce and Pr}$ a high pressure phase (fcc γ phase) of the rare earth is also present similar to melt-spun samples,³ while for the other rare earths, an amorphous phase is formed in addition to $\alpha\text{-Fe}$. Upon annealing of the as-milled powders, RFe_7 -type compounds were formed. XRD patterns of the compounds show no superlattice diffraction peaks related to R_2Fe_{17} -type compounds, which should be at $2\theta \sim 37.5^\circ$ (40.8°) for R_2Fe_{17} with rhombohedral (hexagonal) $\text{Th}_2\text{Zn}_{17}$ structure. The XRD patterns are indexed with the $TbCu_7$ structure of the hexagonal unit cell as shown in Fig. 1(A) for $R=\text{Sm}$. The lattice constants a and c of the compounds were obtained by fitting the XRD patterns. The 1:7 structure is derived by randomly substituting an appropriate amount of the R atoms by pairs of Fe dumbbells. As the dumbbell is introduced along the c axis, the substitution of the Fe dumbbell for R should result in an expansion in the c direction increasing the c/a ratio with increasing Fe concentration. The ratio increases from 0.84 to 0.85 for Gd and Ho when the composition changes from RFe_7 to $RFe_{8.5}$. This result also suggests that the compounds have a range of solubility. The lattice constants and v for the various rare earths are described in Fig. 2 (filled circles). All of the RFe_7 -type compounds can absorb a large amount of nitrogen atoms resulting in a remarkable lattice expansion, $\Delta v/v$, of the structure. The corresponding XRD pattern shifts to low angle as illustrated in Fig. 1(A). a , c , and v for various RFe_7 nitrides are shown in Fig. 2 (open circles). As can be seen in Fig. 2, a , c , and v of the hexago-

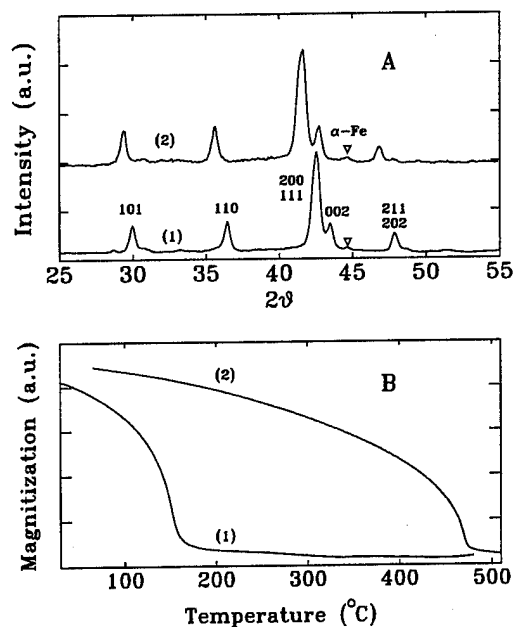

FIG. 1. X-ray diffraction and thermomagnetic scans of SmFe_7 powder annealed at 700 °C for 30 min (1) and its nitride (2).

nal unit cell decrease with increasing atomic number of the rare earths except for Ce which has a different valence state.

B. Magnetic properties

The Curie temperatures, T_c 's, for various RFe_7 -type compounds and their nitrides were obtained from TGAM scans, an example of which is shown in Fig. 1(B) for $\text{R}=\text{Sm}$. The data for all R are shown in Fig. 3. As can be seen from Fig. 3, T_c for the nitride is, on average, ~ 300 °C higher than its corresponding parent RFe_7 compound and the differences in T_c 's among the various nitrides are less remarkable than that among the corresponding RFe_7 parent compounds.

FIG. 2. a , c , and v of RFe_7 -type compounds and their nitrides for various R's.

FIG. 3. Curie temperatures of RFe_7 -type compounds and their nitrides for various R's.

Room temperature saturation magnetizations (M_s 's) and coercivities (H_c 's) for the RFe_7 compounds and their nitrides are listed in Table I. M_s 's for the early rare earths are generally much higher than that for the late rare earths suggesting that the magnetic exchange coupling between the iron sublattice and the R sublattice is ferromagnetic for the early rare earths and antiferromagnetic for the late rare earths, similar to what has been reported for the related structures of R_2Fe_{17} - and $\text{R}(\text{Fe},\text{M})_{12}$ -type compounds (M =structure-stabilizing element).⁴ The coercivity for the SmFe_7 nitride in Table I was obtained by a pulsed-field magnet with 20 T maximum field and is in good agreement with published values.⁵ Besides the SmFe_7 nitride, the nitrides of TbFe_7 , DyFe_7 , and HoFe_7 have high coercivities, as can be seen from Table I. A typical hysteresis loop for the above three types of nitrides is shown in Fig. 4. This is the first time that the high coercivities are observed in RFe_7 compounds other

than for $\text{R}=\text{Sm}$. The hard magnetic behavior of the RFe_7 nitrides are distinct from their R_2Fe_{17} and $\text{R}(\text{Fe},\text{M})_{12}$ counterparts: for R_2Fe_{17} nitrides they are magnetically soft for $\text{R}=\text{Tb}$, Dy , and Ho but hard for $\text{R}=\text{Sm}$, while for $\text{R}(\text{Fe},\text{M})_{12}$ nitrides hard magnets are obtained for $\text{R}=\text{Tb}$, Dy , and Ho but soft for $\text{R}=\text{Sm}$. Although the origin of the hard magnetic behavior needs further investigation, our results suggest a new family of $\text{R}-\text{Fe}$ metastable compounds which are different in both the structure and magnetic properties. Moreover, one can see from Fig. 4 that although the powder is isotropic, the remanence σ_r is substantially higher than $\sigma_s/2$ (σ_s , saturation magnetization). The remarkable enhancement in the remanence ($\sigma_r/\sigma_s=0.64$ for the DyFe_7 nitride) is most likely caused through the magnetic coupling between neighboring grains with a nanocrystalline structure produced by the MA technique.

IV. CONCLUSIONS

RFe_7 compounds of the TbCu_7 structure type through most of the rare earth series have been synthesized by an-

nealing of MA powders. The lattice constants and the volume of unit cell for both RFe_7 compounds and their nitrides decrease with increasing atomic number of the rare earths except for Ce which has a different valence state. This 1:7 structure has a range of solubility with the c/a ratio increasing with Fe content. Nitriding results in a dramatic enhancement of the magnetic properties of the compounds. T_c 's are increased by $\sim 300^\circ\text{C}$ upon nitriding. RFe_7 nitrides with $\text{R}=\text{Sm}$, Tb , Dy , and Ho have high coercivities. The substantial enhancement in the remanence for RFe_7 nitrides with $\text{R}=\text{Tb}$, Dy , and Ho is attributed to the possible magnetic exchange coupling between nanocrystalline grains in the MA powders.

We have investigated the magnetic properties of the ferromagnetic compounds $\text{Pr}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}\text{D}_x$. First, the sample preparation is described and the location of interstitial deuterium atoms is reviewed according to previous neutron diffraction analysis. In this article, we report high field magnetization measurements performed up to 200 kOe in continuous fields, and isothermal magnetization curves measured between 2 and 300 K on oriented powder samples. Below 250 K, an anomaly in the magnetization curves of $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ has been detected. We discuss the influence of hydrogen on this field-induced anomaly, which is strongly temperature dependent and possible origins such as crystal field effects or first order magnetization process. A comparison is made with $\text{Pr}_2\text{Fe}_{17}\text{N}_x$ in which no anomaly was observed. © 1996 American Institute of Physics. [S0021-8979(96)80108-4]

INTRODUCTION

R_2Fe_{17} compounds (R=rare earth metal) are known to crystallize with the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure type or hexagonal $\text{Th}_2\text{Ni}_{17}$ structure type depending on the rare earth size. Most of these compounds are ferromagnetic with rather moderate Curie temperatures (slightly above room temperature). Insertion of light elements such as H, C, or N in the R_2Fe_{17} series has been found to modify the magnetic properties of these compounds, which thus become prospective candidates for metal-bonded permanent magnets. The most spectacular changes are increases of the Curie temperature, T_C , and of the magnetization, M_s , upon interstitial insertion.¹⁻³ Hydrogenated compounds are suitable materials for fundamental studies because a solid solution behavior of hydrogen insertion is observed.^{4,5} This allows modulation of stoichiometry upon reaction and a consequent controlled variation of the magnetic properties.

In the $\text{R}_2\text{Fe}_{17}\text{D}_x$ series, we focus here on the Pr compound investigated by high field magnetic measurements performed up to 200 kOe in a continuous field.

EXPERIMENT

Samples of $\text{Pr}_2\text{Fe}_{17}$ were prepared by induction melting in cold crucible under argon atmosphere and then annealed at 950 °C for 10 days. Standard x-ray diffractometry revealed that the samples are single phase. The diffractograms of the rhombohedral compounds were indexed using the hexagonal multiple cell. Deuteridation was then performed in a dedicated stainless steel autoclave under a deuterium pressure of about 5 MPa leading to a stable hydride. A short thermal activation was needed to initiate the reaction. The deuterium uptake was determined by gravimetric methods, and the accuracy of the interstitial concentration can be estimated to about 2%. The Curie temperature was determined using a homemade Faraday-type torque balance, the powder was sealed in a small silica tube in order to avoid outgassing or oxidation while heating. Magnetic measurements from 4.2 to

300 K were performed using an automatic device equipped with a cryostat and a calorimeter described in detail elsewhere.⁶ The extraction technique was used to measure the magnetization in continuous magnetic fields up to 200 kOe produced by a water-cooled Bitter magnet. No single crystals are available due to the decrepitation process which is known to occur when deuterium is inserted in R_2Fe_{17} compounds. All the samples were sieved down to a mean particle size of 25 μm , the larger grains being of 40 μm . Then the powder was mixed with epoxy resin and subsequently aligned at room temperature using an orientation field of typically 10 kOe.

RESULTS AND DISCUSSION

Details about the structure can be found in Ref. 7; insertion of deuterium induces a drastic increase of the Curie temperature from $T_C=293$ to 531 K for $\text{Pr}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}\text{D}_5$, respectively. The 4.2 K magnetization isotherms of the starting alloy $\text{Pr}_2\text{Fe}_{17}$ and of its corresponding deuteride $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ are shown in Figs. 1 and 2 in the directions parallel and perpendicular to the alignment direction. The anisotropy field is the field that is required to align the moments in the easy magnetization direction from a direction perpendicular to it. It can be seen that at 4.2 K this field is lowered from 140 kOe (Fig. 1) to 110 kOe (Fig. 2) upon deuteridation. Since $\text{Pr}_2\text{Fe}_{17}$ and $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ both exhibit planar anisotropy, the decrease of the anisotropy field reflects a decrease of the planar character of magnetic anisotropy. We also note that the magnetization process along the parallel direction is slightly different in the alloy and the deuterated material. At 4.2 K the deuterated compound saturates for a smaller field and its saturation magnetization is larger by 1.5 μ_B per formula unit. Another noticeable feature is the moment carried by the Pr atoms. A rough estimation of its magnitude can be made from the values of the extrapolated saturation magnetization and assuming a value of 2 μ_B for the iron moments (within the standard deviation of Ref. 7)

FIG. 1. Magnetization isotherms of oriented $\text{Pr}_2\text{Fe}_{17}$ at 4.2 K. The inset is a zoom of the magnetization in the direction perpendicular to the applied field, the arrow points to the anomaly.

equivalent to $34 \mu_B$ for the iron sublattice. Since the saturation magnetization observed is 35.2 and $36.7 \mu_B$ for the alloy and the deuterated compound, respectively, one can deduce a value of $0.6 \mu_B/\text{Pr atom}$ in the alloy, which is well below the free-atom value. The discrepancy with the values published in Ref. 7 may originate from the fact that this estimation assumes a collinear structure, and that the polarization effects are not taken into account. Furthermore, neutron powder diffraction is known to give mainly access to localized magnetic moment ($4f$ contribution in the case of Pr) rather

FIG. 2. Magnetization isotherms of oriented $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ at 4.2 K. The variation of the critical field as a function of temperature is displayed in the inset.

FIG. 3. Details of the magnetization isotherms of $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ in the direction perpendicular to the applied field. The anomaly is defined at the inflection point and is indicated by arrows.

than valence electron magnetism. Unlike neutron powder diffraction, magnetic measurements are leading to an overall magnetization including the valence electrons polarization (i.e., $5d$ electrons of rare earth) that is known to be opposite to that of the $3d$ of iron⁸ and also opposite to that of the $4f$ states in the light rare earth. An underestimation of the $4f$ magnetism is thus expected when using the saturation magnetization without taking into account the valence electron contribution. This contributes to the observed discrepancy in the Pr magnetic moment determined from magnetic measurements and that deduced from neutron diffraction.

The most remarkable feature is the anomaly which occurs in the magnetization curves in the direction perpendicular to the alignment. This anomaly is merely distinguishable in the magnetization curve of the alloy (see inset of Fig. 1) but it is clearly seen in the curves of the deuteride (Figs. 2 and 3).

This anomaly is field induced and disappears near 250 K. The critical field has been defined at the inflection point (arrows on Fig. 3) and its variation as a function of temperature is shown in the inset of Fig. 2.

We now discuss the origin of this anomaly. In this compound, the magnetic anisotropy arises from both the rare earth sublattice and the iron sublattice. A previous study on the $\text{Gd}_2\text{Fe}_{17}\text{H}_x$ system⁹ has shown that hydrogen insertion dramatically decreases the crystal electric field gradient at the rare earth site. We have shown in particular that hydrogen acts on terms such as the second-order parameter A_2^0 and even higher order terms. One can thus expect a significant reduction of the first-order contribution to the rare earth anisotropy. This is consistent with the experimental observation of a decrease of the total anisotropy due to the decrease of the Pr contribution ($\alpha_j < 0$). Since Pr and Nd have both negative α_j (first-order Stevens coefficients), high order

terms in the anisotropy energy have to be taken into account to explain the difference of easy magnetization within the basal plane. By Mössbauer spectroscopy, Gubbens¹⁰ has shown that $\text{Pr}_2\text{Fe}_{17}$ exhibits a particular anisotropy within the basal plane. Unlike $\text{Nd}_2\text{Fe}_{17}$, for which magnetization lies along the $[100]$ direction, $\text{Pr}_2\text{Fe}_{17}$ is found to have its easy magnetization axis along the $[1-10]$ crystallographic direction (referred to as b axis by Gubbens). In particular, Pr has a positive γ_J (higher order Stevens coefficient) whereas that of Nd is negative. All this shows the important role played by the higher order anisotropy terms. Going from $\text{Pr}_2\text{Fe}_{17}$ to the corresponding deuteride a relative increasing contribution of the higher order anisotropy terms is expected since the first-order term vanishes upon insertion of deuterium. This could be at the origin of the strong discontinuous change observed on $\text{Pr}_2\text{Fe}_{17}\text{D}_5$ magnetization curves.

For the deuteride, the huge steplike behavior of the magnetization along the hard axis observed in Figs. 2 and 3 could be interpreted at a microscopic scale as a first-order magnetization process (FOMP). A FOMP manifests itself as a discontinuous change of the magnetization direction in presence of the field applied parallel to a specific crystallographic direction, it is characterized by its critical temperature T_{FOMP} below which the FOMP occurs and by its critical field B_{cr} . The physical origin of the FOMP is that two relative minima appear in the macroscopic free energy (as a function of the angle between a crystalline direction and the magnetization direction) giving way to a jump between very close equilibrium configurations. One or the other minimum may be favored depending on the temperature and the strength of the applied magnetic field. In the $\text{Pr}_2\text{Fe}_{17}$ deuteride, after the step observed on the field dependence of the magnetization, the saturation magnetization is almost reached; this is specific of a so-called type I FOMP as proposed by Asti and Bolzoni.¹¹ The observed critical field at 4.2 K is about 50 kOe. We have already mentioned that there is a slight indication of the same anomaly on the alloy (see Fig. 1). The fact that it is much less visible can be attributed to changes of anisotropy related to changes in the crystal field. It may also be due to

the temperature at which the sample was oriented, temperature which in the case of the alloy lies very close to the Curie temperature and hence makes the orientation less effective. Let us note that no anomaly of that kind has been observed on the nitride $\text{Pr}_2\text{Fe}_{17}\text{N}_3$;⁶ this may be due to the fact that nitrogen, contrarily to deuterium, induces an increase of the crystal electric field gradient acting on the rare earth site, and thus of the rare earth contribution to anisotropy. Finally, we mention that original features of the magnetization of $\text{Pr}_2\text{Fe}_{17}$ deuterides have also been observed in the course of a Mössbauer study as discussed elsewhere in these proceedings.¹²

CONCLUSION

We have shown that a field-induced and temperature-dependent anomaly exists in the magnetization process of the $\text{Pr}_2\text{Fe}_{17}\text{D}_x$ system. It is suggested that it can be interpreted as a first order magnetization process. An interesting comparison can be made with the corresponding nitrogenated system and it suggests that the occurrence of the phenomenon is related to the nature of the interstitial itself.

Structural and magnetic properties of rapidly quenched $(\text{R,Zr})(\text{Fe,Co})_{10}\text{N}_x$ ($\text{R}=\text{Nd,Sm}$)

Institute for Materials Research, Tohoku University, Sendai, Japan

The structural and magnetic properties of $(\text{R,Zr})(\text{Fe,Co})_{10}$ ($\text{R}=\text{Nd,Sm}$) prepared by the rapid-quenching method have been investigated. The presence of zirconium makes it possible to realize a TbCu_7 -type crystal structure with a high c/a ratio of more than 0.87, while the same crystal structure has a c/a ratio of just 0.84–0.85 in the zirconium-free case. The saturation magnetization of crystals having such a high c/a ratio as 0.87 exceeds 1.7 T at room temperature. These materials can be nitrogenated, and remarkable enhancement of magnetocrystalline anisotropy by nitrogenation can be seen in the case of Sm. The magnetic hardening of these nitrogenated materials can be achieved by annealing before nitrogenation. The highest value of $(BH)_{\text{max}}$ obtained so far for the nitrogenated materials is 144 kJ/m^3 (18.0 MGOe). The H_c and B_r values for this sample are 503 kA/m (6.3 kOe) and 1.08 T, respectively. © 1996 American Institute of Physics. [S0021-8979(96)37208-0]

I. INTRODUCTION

Search for new permanent magnet materials has been concentrated on iron-rich rare-earth intermetallic compounds since the discovery of Nd–Fe–B magnets.^{1,2} In binary rare-earth-iron systems, the R_2Fe_{17} alloys have been known as iron-rich compounds and have attracted much attention since Coey and Sun reported on the improvement of their intrinsic magnetic properties by introducing interstitial nitrogen.³

Simultaneously, much effort has been devoted to search for new iron-rich rare-earth compounds in ternary systems. In the course of this search, $\text{R}(\text{Fe,M})_{12}$ with ThMn_{12} -type tetragonal structure ($\text{M}=\text{Al, Si, Ga, Ti, V, Cr, Mn, Mo, W, and Re}$)^{4–9} and in recent years, $\text{R}_3(\text{Fe,M})_{29}$ ($\text{M}=\text{Ti, V, Cr, and Mn}$)¹⁰ with monoclinic structure have been found. In these compounds there exists a greater number of iron sites than that of R_2Fe_{17} . However, the elements M, which play an important role in stabilizing these structures, occupy the iron sites and significantly reduce the magnetization which hypothetical compounds RFe_{12} and R_3Fe_{29} might possess.

On the other hand, we have studied the formation of the ThMn_{12} structure in the $\text{R}(\text{Fe,Si})_{12}$ system and found that most of the zirconium occupies the rare-earth site and facilitates the formation of this structure.¹¹ This result seems to suggest that the zirconium in the rare-earth site, like the above-mentioned M elements in the iron site, might also stabilize the iron-rich phases.

The objective of this research is to find new permanent magnet materials with high iron concentration and therefore with high saturation magnetization. In this respect, we have focused our attention on the iron-rich composition in the R–Zr–Fe ternary system and have investigated the structural and magnetic properties of $(\text{R,Zr})\text{Fe}_{10}$ and $(\text{R,Zr})(\text{Fe,Co})_{10}$ alloys ($\text{R}=\text{Nd,Sm}$) prepared by the rapid-quenching method. We have also extended our research to their nitrogenated alloys.

II. EXPERIMENT

Ingots of the $(\text{R,Zr})(\text{Fe,Co})_{10}$ ($\text{R}=\text{Nd,Sm}$) were prepared by arc-melting in an argon gas atmosphere. Rapidly quenched ribbons were obtained from these ingots by conventional melt spinning with a copper roll in an argon gas atmosphere. The roll velocity was 40 m/s. Some of these ribbons were annealed in vacuum at 670–750 °C for 15 min. Part of the prepared ribbons was pulverized to a diameter smaller than 22 μm and nitrogenated in a 1 atm N_2 atmosphere at 420–460 °C for 8–140 h. The crystal structure of these ribbons and powders were determined by x-ray diffraction (XRD) analysis using $\text{Cu K}\alpha$ radiation. Magnetic measurements were performed using VSM at room temperature. In particular, the magnetization curves were measured with applied fields up to 12 MA/m (150 kOe) at the High Field Laboratory of Tohoku University.

III. RESULTS AND DISCUSSION

Figures 1(a) and (b) show (XRD) patterns for rapidly quenched NdFe_{10} and $\text{Nd}_{0.5}\text{Zr}_{0.5}\text{Fe}_{10}$ alloy ribbons, respectively. These patterns indicate that both of them consist mainly of the TbCu_7 -type crystal structure with a certain amount of $\alpha\text{-Fe}$. Lattice parameters of the TbCu_7 structure are $a=0.493 \text{ nm}$, $c=0.416 \text{ nm}$, $c/a=0.845$ for NdFe_{10} and $a=0.484 \text{ nm}$, $c=0.423 \text{ nm}$, $c/a=0.873$ for $\text{Nd}_{0.5}\text{Zr}_{0.5}\text{Fe}_{10}$. This result shows that zirconium substitution stabilizes the TbCu_7 structure with an extremely high c/a ratio.

It is known that the $\text{Th}_2\text{Zn}_{17}$ and ThMn_{12} structure can be transformed to the TbCu_7 structure. According to Katter *et al.*,¹² the c/a ratio of the TbCu_7 structure transformed from the $\text{Th}_2\text{Zn}_{17}$ structure is 0.840 and that from the ThMn_{12} structure is 0.894. The c/a ratio of the TbCu_7 structure appeared in rapidly quenched NdFe_{10} and $\text{Nd}_{0.5}\text{Zr}_{0.5}\text{Fe}_{10}$ alloy ribbons takes intermediate values between that of the $\text{Th}_2\text{Zn}_{17}$ and that of the ThMn_{12} structure. Therefore, the iron concentration in the TbCu_7 structure appeared in these alloys

FIG. 1. X-ray diffraction patterns for rapidly quenched alloy ribbons: (a) NdFe_{10} ; (b) $(\text{Nd}_{0.5}\text{Zr}_{0.5})\text{Fe}_{10}$; and (c) $(\text{Nd}_{0.5}\text{Zr}_{0.5})(\text{Fe}_{0.7}\text{Co}_{0.3})_{10}$.

should also take the intermediate values between them and the obtained high c/a crystal by zirconium substitution should have a greater number of the dumbbell arrangements of iron atoms. The TbCu_7 structure with high c/a of more than 0.87 was also obtained in the case of Sm and the amount of $\alpha\text{-Fe}$ could be decreased by a partial replacement of iron by cobalt in both cases of Nd and Sm.

Figure 1(c) shows the x-ray diffraction pattern for rapidly quenched $(\text{Nd}_{0.5}\text{Zr}_{0.5})(\text{Fe}_{0.7}\text{Co}_{0.3})_{10}$. As shown in this figure, the intensity of the $\alpha\text{-Fe}$ peak is relatively low. Considering this result and composition of this cobalt substituted alloy, we conclude that most of zirconium occupies the rare-earth site in the TbCu_7 structure. These materials can be nitrogenated, resulting in a lattice expansion without a change in the crystal structure. Their c/a ratio is almost the same as that before nitrogenation.

Magnetization measurement was made for the rapidly quenched $(\text{Nd}_{0.5}\text{Zr}_{0.5})(\text{Fe}_{0.7}\text{Co}_{0.3})_z$ alloy ribbons having the TbCu_7 structure with various c/a values in order to make clear the relation between the saturation magnetization (M_s) and the c/a ratio. To change the c/a ratio, a series of compounds having different z values were prepared. Figure 2 shows the magnetization curves at room temperature for these alloys and M_s as a function of the c/a ratio. It can be seen from Fig. 2(b) that M_s increases linearly with increasing c/a and exceeds 1.7 T for high c/a crystals. As shown in Fig. 2(a), the magnetocrystalline anisotropy of these alloys seems to be relatively low. Therefore, we nitrogenated these alloys in order to enhance the magnetocrystalline anisotropy. Figure 3 shows the magnetization curves of rapidly quenched $(\text{R}_{0.75}\text{Zr}_{0.25})(\text{Fe}_{0.7}\text{Co}_{0.3})_{10}$ alloy ribbons

FIG. 2. (a) Magnetization curves for the rapidly quenched $(\text{Nd}_{0.5}\text{Zr}_{0.5})(\text{Fe}_{0.7}\text{Co}_{0.3})_z$ alloys having TbCu_7 structure with various c/a and (b) the saturation magnetization as a function of c/a .

($\text{R}=\text{Nd}, \text{Sm}$) and their nitrogenated powders. Remarkable enhancement of the magnetocrystalline anisotropy by nitrogenation can be seen only in the case of Sm. The values of M_s and anisotropy field (H_A) were estimated by means of the M vs H^{-2} plots, using the high field part of the magnetization curves. The values obtained were $M_s=1.76$ T, $H_A=3.2$ MA/m (40 kOe) for $(\text{Nd}_{0.75}\text{Zr}_{0.25})(\text{Fe}_{0.7}\text{Co}_{0.3})_{10}\text{N}_x$ and $M_s=1.70$ T, $H_A=6.2$ MA/m (77 kOe) for $(\text{Sm}_{0.75}\text{Zr}_{0.25})(\text{Fe}_{0.7}\text{Co}_{0.3})_{10}\text{N}_x$. It is concluded that nitrogenated alloy in the case of Sm with the TbCu_7 structure having c/a as high as 0.87 seems to be promising for high performance permanent magnet materials because of their excellent intrinsic magnetic properties.

Next, attention was paid to the hard magnetic properties of the Sm-containing materials which consist mainly of TbCu_7 -type compounds with a high c/a ratio. These rapidly quenched and subsequently nitrogenated materials typically have rather low coercivity of about 240 kA/m (3 kOe). Therefore, we investigated the annealing effect on rapidly quenched ribbons before nitrogenation in order to improve the hard magnetic properties.

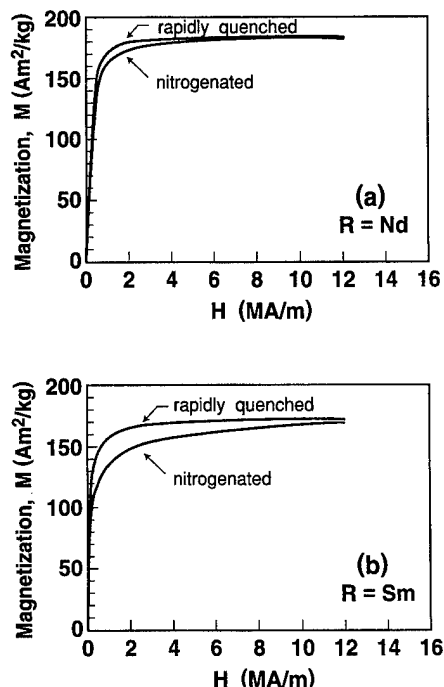

FIG. 3. Magnetization curves for the rapidly quenched ($R_{0.75}Zr_{0.25}$)($Fe_{0.7}Co_{0.3}$)₁₀ alloy ribbons and their nitrogenated powders: (a) $R=Nd$ and (b) $R=Sm$.

Figure 4 shows the energy product $(BH)_{\max}$, the remanence B_r , and the coercivity iH_c for rapidly quenched, annealed, and then nitrogenated ($Sm_{0.75}Zr_{0.25}$)($Fe_{0.7}Co_{0.3}$)_{9.3} which has the $TbCu_7$ structure with the c/a of 0.867 as a

FIG. 4. Energy product $(BH)_{\max}$, remanence B_r , and coercivity iH_c for rapidly quenched, annealed, and nitrogenated ($Sm_{0.75}Zr_{0.25}$)($Fe_{0.7}Co_{0.3}$)_{9.3} as a function of the annealing temperature.

function of the annealing temperature T_a . As seen in Fig. 4, the value of iH_c monotonously increases with increasing T_a in the range 670–750 °C. On the other hand, the values of B_r and $(BH)_{\max}$ first increase with increasing T_a and reach the maximum at $T_a=700$ °C. By further increasing T_a above 700 °C, both B_r and $(BH)_{\max}$ decrease. From the result of the x-ray diffraction study, it was confirmed that the initial crystal structure was maintained after annealing although α -Fe appeared above 700 °C remarkably. Decreases in B_r and $(BH)_{\max}$ above 700 °C may be caused by the appearance of α -Fe due to partial decomposition of the main phase during annealing. The maximum $(BH)_{\max}$ of 144 kJ m^{-3} (18.0 MGOe) was obtained for a sample which was annealed at 700 °C and subsequently nitrogenated. The iH_c and B_r values for this sample are 503 kA/m (6.3 kOe) and 1.08 T, respectively.

It should be noted here that B_r for this sample is greater than $M_s/2$ although the sample is magnetically isotropic. This result presumably reflects that the grain of the $TbCu_7$ phase are magnetically coupled with each other or with some α -Fe grains and thus B_r is enhanced above $M_s/2$.

IV. CONCLUSIONS

(1) In preparing rapidly quenched rare-earth-iron alloys, zirconium substitution for the rare-earth ions stabilizes the $TbCu_7$ structure with extremely high c/a ratio.

(2) The saturation magnetization of $TbCu_7$ -type compounds increases with increasing c/a ratio and exceeds 1.7 T in a crystal having such high c/a as 0.87.

(3) Remarkable enhancement of the magnetocrystalline anisotropy by nitrogenation can be seen in the case of Sm-containing samples. The intrinsic magnetic properties of ($Sm_{0.75}Zr_{0.25}$)($Fe_{0.7}Co_{0.3}$)₁₀N_x at room temperature are $M_s=1.70$ T and $H_A=6.2$ MA/m (77 kOe).

(4) In the case of Sm, the magnetic hardening of materials based on $TbCu_7$ -type compounds with high c/a ratio can be achieved by rapid quenching and subsequent nitrogenation, involving an optional annealing before nitrogenation. The highest value of $(BH)_{\max}$ obtained so far for such material is 144 kJ m^{-3} (18.0 MGOe). The iH_c and B_r value for this sample are 503 kA/m (6.3 kOe) and 1.08 T, respectively.

Aligned high magnetization Nd(Fe,Co,Mo)₁₂ films nitrided by N ion implantation

X. R. Qian, H. Hegde, and F. J. Cadieu

Department of Physics, Queens College of CUNY, Flushing, New York 11367

Ion implantation has been used to nitride highly aligned ThMn₁₂-type structure Nd(Fe,Co,Mo)₁₂ film samples. The initial 1-12-type films were made by sputtering with the crystallite *c* axes aligned perpendicular to the film plane. The films were then nitrided to produce fully nitrided 1-12 films, but only for a limited range of N ion doses. Much of the 1-12 phase was made amorphous before full nitriding was observed. It was not possible to thermally anneal the N implanted samples to lower the α -Fe concentration resulting from the N ion bombardment. This is only consistent with the Nd(Fe,Co,Mo)₁₂N phase being metastable. Low temperature heat treatments of the N implanted films at temperatures less than 270 °C produced evidence for Fe₁₆N₂ formation, but little restoration of the 1-12 phase. For heat treatments at temperatures of 270 °C and above no evidence of Fe₁₆N₂ was detected. These results indicate that it is not possible to produce nitrided ThMn₁₂ films with Fe₁₆N₂ inclusions by ion implantation. © 1996 American Institute of Physics. [S0021-8979(96)37308-7]

INTRODUCTION

We have reported the synthesis of Nd(Fe,Co,Mo)₁₂N films made by sputtering with the magnetization aligned perpendicular to the film plane. Such films were made with room temperature energy products up to 46.3 MGOe and a low temperature value of 59.6 MGOe at 10 K.¹ Those films were thermally nitrided by heating the films in \approx 500 Torr N₂ gas at temperatures of 550 °C for 1 to 2 h.² The highest energy product films were completely free of any α -Fe contamination. To further increase the available moment of rare earth transition metal compounds, recent studies have studied the use of α -Fe mixed on a nanoscale basis to obtain enhanced saturation and remanent flux density values.³⁻⁵ Generally in such studies isotropic magnetic material has been studied. We have used an alternative procedure which starts with highly crystallographically aligned Nd(Fe,Co,Mo)₁₂ film samples. The possibility of nitriding such samples by N ion implantation was studied. It has been shown that Fe₁₆N₂ films can be made by a two-step process by the N ion implantation of Fe films with a subsequent low temperature heat treatment.⁶ Since thermal nitriding ThMn₁₂ phases often results in some α -Fe increase, an alternative approach to making remanent enhanced magnetic materials could be to use N ion implantation for nitriding and have the α -Fe phase present or created converted to high magnetization Fe₁₆N₂. In this article we have synthesized ThMn₁₂-type structure Nd(Fe,Co,Mo)₁₂ films with the crystallite *c* axes aligned perpendicular to the film plane. Nitriding of these films has then been done by using N ion implantation. Low temperature anneals have then been used to see if α -Fe inclusions could be converted to high magnetization Fe₁₆N₂. The results indicate that it is inherently not possible to use N ion implantation to produce Nd(Fe,Co,Mo)₁₂ N films with Fe₁₆N₂ inclusions due to the metastable nature of the ThMn₁₂ nitrided phases.

EXPERIMENT

Sputtering has been used to synthesize Nd(Fe,Co,Mo)₁₂ ThMn₁₂-type structure films such that the crystallographic *c* axes are oriented perpendicular to the film plane. This

growth method has been previously reported. In contrast to our previous reporting where the films have been thermally nitrided, N ion implantation has been investigated as a possible nitriding method. The N ion implantation has been done by Implant Sciences using 200 KeV N⁺ ions. The samples were nitrided about 7° away from the film normal to minimize any channeling effects either along the crystallite *c* axes or along any columnar growth pattern of the films. The films investigated were 3000 to 5000 Å thick. X-ray diffraction data were obtained using Cu K α radiation.

RESULTS AND DISCUSSION

Figure 1 shows x-ray diffraction traces for a 3500-Å-thick (002) textured Nd(Fe,Co,Mo)₁₂ film that was subjected to 200 keV N ion flux doses of 0, 5.0 e16, 10 e16, 20 e16, and 40 e16 N/cm². The initial film exhibited only the (002) Nd(Fe,Co,Mo)₁₂ line and the two Al₂O₃, 35.15° (104), and 37.78° (110) from the polycrystalline substrate in this angular range. The low dose of 5 e16 N/cm² reduced the 1-12 phase

FIG. 1. The effects of successively higher N ion flux doses in N/cm² is shown for a 3500-Å-thick Nd(Fe,Co,Mo)₁₂ film. The y axis zero for the successive traces has been shifted by 200 counts to separate the traces. The substrate lines from the polycrystalline Al₂O₃ substrate are denoted by the letter S.

FIG. 2. For the same sample of Fig. 1 the x-ray trace in the region of the α -Fe (110) line is illustrated. The y axis for each successive trace has been shifted by 200 counts to separate the traces. The slanted line shows the lattice expansion of the α -Fe phase with the successively increased N doses. The prominent Al_2O_3 (113) line at 43.36° remains unshifted and acts as a reference line.

(002) intensity. For a N dose of $10 \text{ e}16 \text{ N/cm}^2$ a clear shift of the 1-12 (002) line to lower angles, which corresponds to a lattice cell expansion is evident. For a dose of $20 \text{ e}16 \text{ N/cm}^2$ the 1-12 (002) line has shifted to 36.6° . The 1-12 c axis has then shifted from 4.817 \AA for the film as deposited to 4.906 \AA for the nitrided films. This corresponds to a c lattice parameter shift of $+1.8\%$ which is typical for thermally nitrided 1-12 phase films. It should be noted that the volume expansion observed for 1-12 films is normally somewhat larger because of substrate film strain, than that observed in bulk samples. The further dose of $40 \text{ e}16 \text{ N/cm}^2$ has acted to completely amorphize the 1-12 phase.

Figure 2 shows the shifting of the α -Fe (110) line, as indicated by the slanted line, with successively increased N dosage. This shows that the α -Fe lattice expanded with increased N incorporation.

Figure 3 shows x-ray diffraction traces for a 3000-\AA -thick $\text{Nd}(\text{Fe},\text{Co},\text{Mo})_{12}$ film that exhibited a somewhat broader 1-12 (002) line, before and after N ion implantation at a dose of $4 \text{ e}16 \text{ N/cm}^2$. Sections of the N implanted film were then heat treated at temperatures of 150, 200, and 270°C for 24 h. No evidence for the nitrided 1-12 phase recovery was observed following low temperature heat treatments. The Fe_{16}N_2 phase has been shown to be unstable above about 250°C .⁶ For any thermal recovery of the amorphized 1-12 phase following ion bombardment to be consistent with Fe_{16}N_2 inclusions must occur below 250°C . The ThMn_{12} phase was not recovered by such low temperature anneals which would also be consistent with the formation of Fe_{16}N_2 . Some intensity developed for the 200°C heat treatment at 36.1° which would correspond to the (112) Fe_{16}N_2 phase. Annealing at 270°C destroyed the 36.1° peak with a new peak forming at 38.2° . No peak developed at 28.35° which would correspond to the Fe_{16}N_2 (002) reflection. That peak would be strong in these textured films only if the Fe_{16}N_2 was textured with the c axes perpendicular to the film plane.

FIG. 3. The effects of a $4 \text{ e}16 \text{ N/cm}^2$ N ion flux dose and then subsequent low temperature heat are shown for a 3000-\AA -thick $\text{Nd}(\text{Fe},\text{Co},\text{Mo})_{12}$ film. The y axis zero for the successive traces has been shifted by 200 counts to separate the traces. The substrate lines from the polycrystalline Al_2O_3 substrate are denoted by the letter S.

The results of Fig. 1 indicate that the 1-12 phase can be nitrided by N implantation. The nitriding is sensitive to the N implant dose with much of the 1-12 phase made amorphous before substantial nitriding was observed. In our experience and that of others it has never been possible to reduce the amount α -Fe present in nitrided $\text{Nd}(\text{Fe},\text{Co},\text{Mo})_{12}$ samples by any thermal heat treatment. This is evidence that the nitrided ThMn_{12} compounds are inherently metastable only. In contrast to this metastable behavior with nitrogen, hydrogen can be reversibly introduced and removed from the samples through thermal cycling without ThMn_{12} phase deterioration. High coercive forces and the highest energy products have only been observed in samples which were completely free of α -Fe. Evidence of Fe_{16}N_2 formation was observed following implantation and then heat treatments at temperatures of less than 270° . No detectable Fe_{16}N_2 remained after the 270°C heat treatment. In addition the fraction of the 1-12 phase could not be recovered at the low temperature anneals required to stabilize the Fe_{16}N_2 phase. Since it has not been possible to nitride the $\text{Nd}(\text{Fe},\text{Co},\text{Mo})_{12}$ samples without appreciable phase disproportionation, it is inherently not possible to anneal the samples and recrystallize the samples into a composite richer in ThMn_{12} phase than the disproportion level reached during the ion bombardment. Consequently it has not been possible to use N ion implantation to simultaneously obtain well defined nitrided $\text{Nd}(\text{Fe},\text{Co},\text{Mo})_{12}$ phase samples and to simultaneously convert the α -Fe inclusions to high moment Fe_{16}N_2 .

Magnetic and phase transformation studies in $\text{Nd}_{15}\text{DyFe}_{75}(\text{C,B})_9$ cast alloys

A. S. Murthy,^{a)} I. Panagiotopoulos, and G. C. Hadjipanayis

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

Previous studies have shown that high coercivities can be achieved in cast Nd-Fe-C alloys through an annealing heat treatment at 900 °C, which causes a peritectoidal transformation from $\text{Nd}_2\text{Fe}_{17}\text{C}_x$ to $\text{Nd}_2\text{Fe}_{14}\text{C}_x$. We have studied the characteristics of this transformation in cast $\text{Nd}_{15}\text{DyFe}_{75}(\text{C,B})_9$ alloys. Optimum coercivities were obtained by annealing for 6 h at 900 °C. A highly faulted carbide phase was identified in samples annealed for 5 min at 900 °C. From electron diffraction investigations, this phase was identified to be hexagonal with lattice parameters, $a=0.48$ nm and $c=0.81$ nm. The development of coercivity in the various stages of transformation is related to the crystal structure and microstructure developed in the transformation. The presence of α -Fe in samples with increased Fe content leads to reduced coercivities. © 1996 American Institute of Physics. [S0021-8979(96)37408-3]

INTRODUCTION

Cast alloyed materials based on the $\text{R}_2\text{Fe}_{14}\text{C}$ phase have attracted considerable attention in recent years as candidates for permanent magnets.¹⁻⁸ In these materials, the $\text{R}_2\text{Fe}_{14}\text{C}$ phase responsible for high coercivities is obtained upon annealing of the $\text{R}_2\text{Fe}_{17}\text{C}$ phase through a complex peritectoidal transformation. In the Nd-Fe-C system, the $\text{Nd}_2\text{Fe}_{14}\text{C}$ phase is not stable above 900 °C, and transforms peritectically to the equilibrium $\text{R}_2\text{Fe}_{17}\text{C}$ phase at higher temperatures. The solid peritectoidal transformation involving $\text{Nd}_2\text{Fe}_{17}\text{C}$, the ternary χ phase⁸ and Fe to $\text{R}_2\text{Fe}_{14}\text{C}$ is sluggish, and requires very long annealing times for the completion. Addition of boron in small amounts is reported to have the beneficial effects of enhancing the kinetics of the $\text{Nd}_2\text{Fe}_{17}$ to $\text{Nd}_2\text{Fe}_{14}\text{C}$ transformation as well as strengthening the phase stability of the $\text{Nd}_2\text{Fe}_{14}\text{C}$ phase by increasing the peritectic transformation temperature.

The phase transformation characteristics and the magnetic properties observed at different stages of annealing are of considerable interest. In this study, we have undertaken such an effort by investigating the phases with transmission electron microscopy (TEM) and x-ray diffraction (XRD), and correlating them with the corresponding magnetic properties in $\text{Nd}_{15}\text{DyFe}_{75}(\text{C,B})_9$ samples. The effects of composition and annealing times and temperatures were evaluated to obtain optimal coercivities in samples with increased iron content.

EXPERIMENT

Nd-Dy-Fe-C-B alloys with various compositions were prepared by arc-melting the constituent elements in an Ar atmosphere. The samples were annealed in evacuated quartz tubes at temperatures from 800 to 950 °C for time intervals ranging from 2 min to 3 days.

The hysteresis loops were measured in a vibrating sample magnetometer (VSM) with a maximum field of 20 kOe. Magnetization measurements in higher fields were done in a superconducting quantum interference device (SQUID) magnetometer with a maximum field of 55 kOe. X-ray dif-

fraction (XRD) spectra were measured with Cu $K\alpha$ radiation in a Philips APD3520 diffractometer. The microstructural investigations were carried out using a Jeol JEM 2000FX transmission electron microscope.

RESULTS AND DISCUSSION

The as-cast samples consist of a mixture of the 2:17 phase and α -Fe as indicated by x-ray (Fig. 1) and electron diffraction results and have coercivities of a few Oe. The grain size in these samples was estimated by TEM studies to be in the range of 1–5 μm . For our present studies on the transformation behavior of a sample with composition $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$, an annealing temperature of 900 °C was chosen, and the annealing time was varied from 2 min to 1 h (Fig. 2). Coercivities of 8.5 kOe were developed after annealing at 900 °C for 6 h (Fig. 3). There was no significant change in the magnitude of the coercivity in the samples annealed for extended periods of time up to several days.

The crystal structure of the phase in these high coercivity samples was identified to be the $\text{Nd}_2\text{Fe}_{14}\text{C}$ phase (Fig. 4). The precipitation of the 2:14:1 phase occurs very fast as

FIG. 1. X-ray diffraction pattern of an as-cast $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$ sample indicating the existence of a mixture of the 2:17 phase and α -Fe. The hysteresis loop of the same sample is shown in the inset.

^{a)}Present address: Intel Corporation, D1-73, Hillsboro, OR 97124-6497.

FIG. 2. Coercivity as a function of annealing time for $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$ samples annealed at 900 °C.

indicated by the rapid increase of H_c . After 30 min of annealing the sample has half the maximum coercivity attainable in these samples.

The microstructure in these samples consisted of large grains of $\text{Nd}_2\text{Fe}_{14}\text{C}$ phase with occasional and often smaller grains of a highly faulted phase, a feature similar to that observed by Zhang *et al.* in a different system containing a high amount of Dy.⁴ The phase is observed at grain boundaries and triple grain junctions. Figure 5 shows a bright field image of a $\text{Nd}_2\text{Fe}_{14}\text{C}$ grain adjacent to a grain consisting of high density planar faults. It was observed that in samples annealed for shorter periods of time, the volume fraction of the faulted phase increased significantly. A corresponding decrease in the value of the coercivity may be noticed from Fig. 2.

The crystal structure of the faulted phase is of considerable interest. This was determined by employing a procedure similar to that described in Ref. 4. First, three electron diffraction patterns sharing a common crystal axis were obtained. The patterns are shown in Fig. 6. These diffraction patterns are of respective zone axes, [010], [110], and [210] all sharing a common axis with reciprocal lattice vector

FIG. 4. X-ray diffraction pattern of an $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$ sample annealed at 900 °C for one day indicating the existence of tetragonal 2:14:1 phase.

along (001). Following an analysis carried out very similarly to that described in Ref. 4, the structure of this faulted phase is analyzed to be also hexagonal. The lattice parameters a and c were obtained by making use of the lattice parameter a from a pattern for which the camera length was determined from a known 2:14:1 diffraction pattern. The final result indicates that $a=0.48$ nm and $c=0.81$ nm which gives a ratio $c/a \sim 1.7$ compared to the value of 1.45 of the 2:17 phase.

The hexagonal carbide phase observed in our samples is a metastable phase, which readily forms from the 2:17 phase upon annealing at 900 °C for short periods of time. Its volume fraction decreases with increasing annealing times, concomitant with an increase in the volume fraction of the tetragonal $\text{Nd}_2\text{Fe}_{14}\text{C}$ phase. Presence of any other carbide phase could not be ascertained in these studies.

Attempts were made to increase the saturation magnetization of the alloys by increasing the Fe content. Figure 7 shows H_c as a function of at. % Fe for samples annealed at 900 °C for one day. XRD data reveal the presence of α -Fe peaks in samples with increased Fe content leading to this drastic reduction of H_c . The inset in Fig. 6 shows the de-

FIG. 3. Hysteresis loop of a $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$ sample annealed at 900 °C for 6 h.

FIG. 5. Bright field image of a $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$ sample annealed at 900 °C for 30 min.

FIG. 6. Electron diffraction patterns sharing a common crystal axis were obtained. The respective zone axes are (a) [010], (b) [110], and (c) [210].

pendence of H_C on the annealing time for a $\text{Nd}_{12.6}\text{Dy}_{0.8}\text{Fe}_{79}(\text{C}_{0.95}\text{B}_{0.05})_{7.6}$ sample. The maximum attainable coercivity is significantly reduced (2.5 kOe) and corresponds to an annealing time of only 10 min.

CONCLUSIONS

As-cast $\text{Nd}_{15}\text{DyFe}_{75}(\text{C}_{0.95}\text{B}_{0.05})_9$ samples consist of a mixture of the 2:17 phase and α -Fe and upon annealing at temperatures around 900 °C a peritectoidal transformation from 2:17 to 2:14:1 occurs. A highly faulted carbide metastable phase was identified in the early stages of this transformation. From electron diffraction investigations, this phase was identified to be hexagonal with lattice parameters, $a=0.48$ nm and $c=0.81$ nm. After 6 h of annealing these samples showed coercivities of 8.5 kOe. In samples with

FIG. 7. H_C as a function of at. % Fe for samples annealed at 900 °C for one day. The inset shows the dependence of H_C on the annealing time for a $\text{Nd}_{12.6}\text{Dy}_{0.8}\text{Fe}_{79}(\text{C}_{0.95}\text{B}_{0.05})_{7.6}$ sample.

higher at. % Fe the magnetization is increased but attainable coercivity is significantly reduced due to the existence of larger grains of α -Fe.

Characteristics of $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds prepared from ball-milled blends of $\text{Sm}_2\text{Fe}_{17}$ and graphite

O. Mao, J. O. Ström-Olsen, Z. Altounian, and J. Yang

Department of Physics, Centre for the Physics of Materials, McGill University, Montréal, Québec H3A 2T8, Canada

A series of $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ ($x=0-6$, nominal) interstitial compounds were synthesized by blending $\text{Sm}_2\text{Fe}_{17}$ and graphite in a ball mill followed by annealing of the sample powders at 450°C for 10 h. X-ray structural analyses show that the lattice constants and the unit cell volume, v , of the carbides increases with x almost linearly up to $x=2.5$ and become constant above $x=3.0$. The Curie temperature, T_c , linearly increases with x up to $x=1.7$ and saturates for $x>2.0$. The saturation values of lattice expansion, $\Delta v/v$, and T_c are 6.1% and 403°C , respectively. $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ powders synthesized with this technique are highly anisotropic. Coercivities for powders with $x>2.2$ are 0.8 T at room temperature. A coercivity of 1.6 T has been achieved in such powders after nitriding.

I. INTRODUCTION

Introduction of interstitial nitrogen and/or carbon atoms into $\text{Sm}_2\text{Fe}_{17}$ intermetallic compound of the $\text{Th}_2\text{Zn}_{17}$ structure type results in a dramatic enhancement of the magnetic properties of this compound and turns it into a promising starting material for permanent magnet application.¹ There have been several preparation techniques for the interstitial compounds of the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ -type: (i) direct alloying (DA) with carbon above the melting temperature followed by either $1000-1200^\circ\text{C}$ annealing² or melt-spinning,³ (ii) absorbing carbon through the gas-solid reaction (GSR) of the $\text{Sm}_2\text{Fe}_{17}$ compound with a hydrocarbon gas,⁴ or (iii) through the solid-solid reaction (SSR) with carbon from the pure solid state.⁵ Among the three techniques, the first two (DA and GSR techniques) are widely used in the research for interstitial modification of the rare earth-iron intermetallic compounds. The DA technique produces carbides with carbon content <1.5 atoms per formula unit due to the metastable nature of the $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ with high carbon concentration, whereas the GSR technique leads to an almost fully carbided compound corresponding to a carbon content of 2–2.5 per formula unit. Few results have been reported for the SSR technique. To prepare the carbide by the SSR technique, $\text{Sm}_2\text{Fe}_{17}$ powders are usually blended with an excess amount of solid carbon and heated to $500-600^\circ\text{C}$ to start the SSR.^{5,6} This technique also produced fully carbided $\text{Sm}_2\text{Fe}_{17}$ powders similar to the GSR technique. The intermediate carbon concentrations x between 1.5 and 2 has not been reported previously. In addition, an abrupt change of lattice constants, both a and c axes, occurs in the concentration range of $1.5 < x < 2.0$.^{7,8} On the other hand, recent studies⁹ for the intermediate nitrogen concentrations ($0 < y < 3.0$) in $\text{Sm}_2\text{Fe}_{17}\text{N}_y$ compounds report no abrupt change of the lattice constants. It is interesting, therefore, to study $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ compounds in the whole carbon concentration range with self-consistent samples. In this contribution we report the synthesis, structure, and magnetic properties of $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ interstitial compound with the SSR technique.

II. EXPERIMENTAL TECHNIQUES

The $\text{Sm}_2\text{Fe}_{17}$ compound was prepared by melting the constituents in a cold crucible induction furnace. Purity of Fe and Sm were 99.99 wt % and 99.9 wt %, respectively. An excess of 15% Sm (corresponding to a starting composition of $\text{Sm}_{2.3}\text{Fe}_{17}$) was added to compensate for Sm loss during melting. For homogeneity the ingots were melted four times. The as-prepared alloy were annealed at 1150°C for 5 h under an Ar atmosphere to produce an almost single phase $\text{Sm}_2\text{Fe}_{17}$ alloy. The resulting $\text{Sm}_2\text{Fe}_{17}$ ingot and a pure graphite were crushed to coarse powder of size <0.5 mm and loaded to a hardened steel vial and sealed. The blend of $\text{Sm}_2\text{Fe}_{17}$ and graphite were prepared by ball milling (BM) appropriate amounts of the constituents. The crushing, weighing, mixing, loading, and sealing procedures were performed in a specially designed glove box with oxygen and humidity levels of <1 ppm. The ball milling was carried out in a high energy SPEX-8000 Mixer/Mill. The hardened steel balls used for BM were 4 mm in diameter. Ball-to-material ratio was kept at 1:1 as higher ratios led to decomposition of the compound. Carbiding of the powders was carried out by annealing the sample in a quartz tube sealed in the glove box. For structural analysis, x-ray diffraction (XRD) was performed in an automated Nicolet-Stöe powder diffractometer with graphite monochromated $\text{Cu } K_\alpha$ radiation. The Bragg peaks of the diffraction pattern were fitted with the Cauchy distribution function

$$I = \frac{I_0}{\{1 + [2(x - x_0)/B]^2\}}, \quad (1)$$

where, I_0 is the intensity, B the full width at half-maximum and x_0 the peak position. Fitting all the Bragg peaks in the range of $2\theta = 20^\circ - 55^\circ$ gave high accuracy in determining a and c of the hexagonal unit cell that describes the rhombohedral $\text{Th}_2\text{Zn}_{17}$ structure. The width of the Bragg peak gives the average grain sizes of the powder by using the Scherrer equation

$$B(2\theta) = \frac{0.94\lambda}{L \cos \theta}. \quad (2)$$

FIG. 1. X-ray diffraction (A) and thermomagnetic (B) scans: (1) $\text{Sm}_2\text{Fe}_{17}$ ingot; (2)–(5) powders ball milled for 20 (2), 50 min (3), 2 h (4) and 5.5 h (5) followed by annealing at 450 °C for 10 h.

The Curie temperature, T_c , was measured by thermomagneto-metry using a Perkin–Elmer thermogravimetric analyzer (TGA-7) in a small magnetic field gradient (TMA).

III. RESULTS AND DISCUSSION

The starting $\text{Sm}_2\text{Fe}_{17}$ ingot prepared by 1150 °C annealing is almost single phase except for the presence of very small amount of $\alpha\text{-Fe}$ and SmFe_3 phases, as shown by the XRD [curve 1 in Fig. 1(A)]. XRD measurements on ball milled $\text{Sm}_2\text{Fe}_{17}$ /graphite powders show no noticeable change in the lattice constants except a broadening of the Bragg peaks due to a finer grain size and severe lattice strain generated by BM. The carbiding reaction starts in the blend at temperatures above 300 °C. The metastable $\text{Sm}_2\text{Fe}_{17}$ carbide tends to decompose when it is heated to above 500 °C. The heat treatment condition usually used to form the carbides is 450 °C for 10 h. We have tried to anneal blends prepared with various milling times. Annealing of short-time-milled blends gives rise to partial carbiding of the sample. Curves 2 and 3 in Fig. 1(A) and 1(B) indicate a distribution of lattice constants and T_c caused by the nonuniform carbon distribution in the sample. Full carbiding occurs in powders milled longer than 2 h. Full carbiding of the sample with milling times longer than 2 h is further confirmed by comparing to the sample with the same carbon content prepared by the DA technique: TMA curves 2 and 3 in Fig. 2 are essentially identical. From the widths of the Bragg peaks (subtracting out the broadening due to the intrinsic resolution of the diffractometer and the strain in the lattice), the grain sizes are estimated to be 80 nm and 40 nm for powders milled 2 h and 5.5 h, respectively. The faster carbiding process in powders with longer milling time may be due to the formation of nanocrystallites resulting in an enhancement of carbon diffu-

FIG. 2. Thermomagnetic scans: (1) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ ingot (prepared by DA technique), (2) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ ingot ball milled for 3 h and (3) $\text{Sm}_2\text{Fe}_{17}\text{C}_{0.5}$ prepared by SSR technique. Inset shows (4) $\text{Sm}_2\text{Fe}_{17}$ ingot and (5) $\text{Sm}_2\text{Fe}_{17}$ ingot ball milled for 3 h. The dashed lines are guidelines showing how to determine T_c 's from the thermomagnetic measurements.

sion through grain boundaries. It is noticed that TMA measurements show a wider transition region and a higher T_c (20–30 °C higher) in the BM sample than in the ingot for both $\text{Sm}_2\text{Fe}_{17}$ carbides and pure binary alloy (inset in Fig. 2). This effect is caused by the defects generated by BM. Longer milling time results in higher $\alpha\text{-Fe}$ content due to the tendency of decomposition of the compound. The dependence of lattice constants and the unit cell volume, v , on the nominal carbon concentration is plotted in Fig. 3(A)–3(C). v increases almost linearly with x up to three, while the increase of T_c saturates at 2.0 as shown in Fig. 3(D). The saturation values of lattice expansion, $\Delta v/v$, and T_c are 6.1% and 403 °C, respectively, shown in Fig. 3(C) and 3(D). As carbon or nitrogen interstitials occupy the 9(e) sites in the R_2Fe_{17} structures of the $\text{Th}_2\text{Zn}_{17}$ type, the maximum carbon or nitrogen content is three atoms per formula unit. It has been

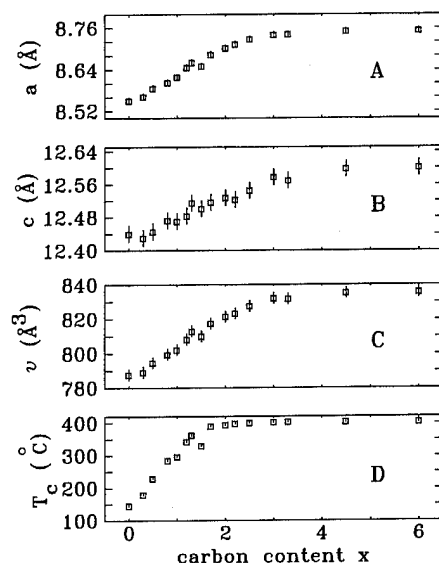

FIG. 3. Dependences on the nominal carbon concentration x of (A) a , (B) c , (C) v , and (D) T_c .

FIG. 4. XRD patterns of magnetically aligned $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ powder.

reported that GSR produces $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ with $x=2-2.5$. Since a carbon layer may exit on the particle surfaces, and does not contribute to the interstitial modification, this makes it difficult to determine the actual carbon content in $\text{Sm}_2\text{Fe}_{17}$ carbide, even in the samples prepared with GSR. The actual carbon concentration in our carbide sample needs further investigation.

Finally, this technique was explored as a processing routine to prepare anisotropic $\text{Sm}_2\text{Fe}_{17}$ powders. XRD measurements on magnetically aligned $\text{Sm}_2\text{Fe}_{17}$ carbide powders show the highly anisotropic nature of the powder as shown in Fig. 4. The presence of graphite during BM separates the $\text{Sm}_2\text{Fe}_{17}$ particles effectively because graphite forms coating layers on the particle surfaces due to its particular layered-structure. BM favors the formation of a fine microstructure giving rise to high coercivity. $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ ($x>2.2$) powders show coercivities >0.8 T at room temperature. A coercivity of 1.6 T has been achieved in such powders after nitriding.

IV. CONCLUSIONS

Annealing of blends of $\text{Sm}_2\text{Fe}_{17}$ and graphite prepared by BM at 450 °C for 10 h results in carbiding of the $\text{Sm}_2\text{Fe}_{17}$ compounds. Structural measurements show that the lattice constants and the unit cell volume, v , increase with carbon concentration x almost linearly up to $x=2.5$ and become constant above $x=3$. Magnetic measurements indicate that T_c increases linearly with x up to $x=1.7$ and saturates for $x>2.0$. The saturation values of $\Delta v/v$ and T_c are 6.1% and 403 °C, respectively. $\text{Sm}_2\text{Fe}_{17}\text{C}_x$ powders prepared with the present technique are highly anisotropic. Samples with high coercivities has been synthesized.

Exchange and crystal-field interactions in $R_3(\text{Fe,Ti})_{29}$ and $R_3(\text{Fe,Ti})_{29}\text{N}_y$ ($R=\text{Nd,Sm}$)

Hong-Shuo Li, D. Courtois, and J. M. Cadogan

School of Physics, The University of New South Wales, Sydney 2052, Australia

A quantitative analysis of the available magnetization data on the $R_3(\text{Fe,Ti})_{29}$ and $R_3(\text{Fe,Ti})_{29}\text{N}_y$ ($R=\text{Nd,Sm}$) compounds have been carried out. The two R sites of $R_3(\text{Fe,Ti})_{29}$ compounds have opposite signs of their leading crystal-field coefficient A_{20} ; namely, $A_{20}<0$ for the 4e site (2:17 like) and $A_{20}>0$ for the 2a site (1:12 like) (site notation is that of the space group $P2_1/c$). A R-Fe exchange coefficient of $285\pm 5\mu_0$ and crystal field coefficients $A_{20}(2a)=+16\text{ K } a_0^{-2}$ and $A_{20}(4e)=-25\text{ K } a_0^{-2}$ were obtained. The type-II first-order magnetization processes observed in both $\text{Nd}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ and $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ have been well reproduced: $\mu_0 H_{\text{cr}}=2.4\text{ T}$ for $R=\text{Nd}$ at 5 K (observed $\sim 2\text{ T}$), and $\mu_0 H_{\text{cr}}=3.0\text{ T}$ for $R=\text{Sm}$ at 4.2 K ($\sim 3.2\text{ T}$). Based on the bonding charge model, we estimate that the values of $A_{20}(4e)$ and $A_{20}(2a)$ for the fully nitrated 3:29 compounds are $A_{20}(4e)=-187\text{ K } a_0^{-2}$ and $A_{20}(2a)=-184\text{ K } a_0^{-2}$. Our calculations show that $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_y$ nitrides become uniaxially anisotropic for $y\geq 2$ and a maximum room temperature uniaxial anisotropy field of 11.4 T for fully nitrated $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_4$ is predicted which compares well with the experimental values which lie in the range 10.7–13 T. © 1996 American Institute of Physics. I. INTRODUCTION

The ternary $R_3(\text{Fe,Ti})_{29}$ (3:29) phase has a monoclinic $\text{Nd}_3(\text{Fe,Ti})_{29}$ structure with the space group $P2_1/c$ (Ref. 1 and 2) (its site notation is used throughout this article); recently it was proposed that the structure can be described more accurately with the space group $A2/m$.³ This structure is an intermediate structure between the well known rhombohedral $\text{Th}_2\text{Zn}_{17}$ (2:17R) and tetragonal ThMn_{12} (1:12) structures, and consists of a combination of the 2:17R and 1:12 segments in a ratio of 1:1.¹ There are two distinct crystallographic R sites, namely 2a and 4e (2a and 4i in the notation of $A2/m$), and fifteen Fe(Ti) sites in the structure. The 4e and 2a R sites have a local environments corresponding to those found in 2:17R and 1:12 structures, respectively.

The new $R_3(\text{Fe}_{1-x}\text{M}_x)_{29}$ ($R=\text{Ce-Dy}$; $M=\text{Ti,V,Cr,Mn,Mo}$) compounds are magnetically ordered with Curie temperatures in the range 322 K (Ce)–524 K (Gd).^{4–12} It has been shown that after introduction of interstitial N or C atoms, the Curie temperature is enhanced to $\sim 700\text{ K}$ in $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{X}_y$ ($X=\text{N,C}$) (Ref. 3, 4, 6, and 11–15) which is comparable to that of $\text{R}_2\text{Fe}_{17}\text{N}_y$, 740 K.¹⁶ The room temperature saturation magnetization, $\mu_0 M_s \sim 1.5\text{ T}$, is also close to that of $\text{Nd}_2\text{Fe}_{17}\text{N}_y$, $\mu_0 M_s = 1.45\text{ T}$. In fact, significant coercivity, has been developed, reaching 0.7–0.85 T in $\text{Sm}_3(\text{Fe}_{1-x}\text{M}_x)_{29}\text{N}_y$ (Ref. 13 and 14) and 0.3 T in $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{C}_y$.¹⁵ These promising magnetic properties suggest that the new $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_y$ compounds might be alternative hard nitride magnets to $\text{Sm}_2\text{Fe}_{17}\text{N}_{3-\delta}$ (Ref. 16) and $\text{NdFe}_{11}\text{TiN}_{1-\delta}$.¹⁶

In order to understand the magnetocrystalline anisotropy of rare earth sublattices in the $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ series, we previously estimated the leading crystal-field coefficients A_{20} by the simple point charge model.¹⁷ We showed that two R sites have opposite signs of A_{20} ; namely, $A_{20}<0$ for the 4e site (2:17 like) and $A_{20}>0$ for the 2a site (1:12 like). Thus, it is likely that the competition of the two R sublattices may re-

sult to unusual magnetization behavior. In fact, the magnetization measurements show the existence of the type-II first-order magnetization processes FOMPs in both $\text{Nd}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ (Ref. 5) and $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ (Ref. 7) systems. The magnetization shows an upturn at a critical applied magnetic field of: $\mu_0 H_{\text{cr}} \sim 2\text{ T}$ for $R=\text{Nd}$ at 5 K,⁷ and $\mu_0 H_{\text{cr}} \sim 2\text{ T}$ for $R=\text{Sm}$ at 4.2 K and $\sim 2.2\text{ T}$ at 77 K.

Here, we present a detailed crystal field (CF) analysis of the $R_3(\text{Fe,Ti})_{29}$ and $R_3(\text{Fe,Ti})_{29}\text{N}_y$ ($R=\text{Nd,Sm}$) compounds based on available magnetization data.

II. RESULTS AND DISCUSSION

We have developed a first-principles theoretical model,^{18,19} incorporating exchange and crystal-field interactions, which has been highly successful in explaining the complex magnetic behavior of a large number of rare-earth, iron series including $\text{R}_2\text{Fe}_{14}\text{B}$, RFe_{11}Ti , $\text{R}_2\text{Fe}_{17}(\text{N,C})_x$, and $\text{RFe}_{11}\text{TiN}_x$. The model is based on two coupled equations that describe the Fe and R sublattices. The Fe sublattice is treated classically whereas the R sublattice is treated from first-principles. The single-ion rare-earth Hamiltonian can be expressed as

$$H_R = H_{\text{SO}} + H_{\text{ex}} + H_{\text{cf}} + H_{\text{Zeeman}}, \quad (1)$$

where $H_{\text{SO}} = \lambda \mathbf{L} \cdot \mathbf{S}$ is the spin-orbit coupling. H_{ex} is the exchange term and can be expressed as $H_{\text{ex}} = 2\mathbf{B}_{\text{ex}} \cdot \mathbf{S}\mu_B$, where the exchange field acting on the rare-earth spin \mathbf{S} is given by $\mathbf{B}_{\text{ex}} = -n_{\text{RFe}} \langle M_{\text{Fe}} \rangle H_{\text{cf}}$ is the R^{3+} crystal-field Hamiltonian whose form depends on the local symmetry of the R crystallographic site. In general, H_{cf} can be expressed in terms of the Racah tensor operators U_q^k as follows:

$$H_{\text{cf}} = \sum_{n=0}^6 \sum_{\text{even } q=-k}^k n A_n^q \langle r^k \rangle U_q^k, \quad (2)$$

where $\{A_n^q\}$ are the CF coefficients which reflect the strength and symmetry of the CF interactions. If $J-J$ mixing is neg-

ligible, H_{cf} reduces to the familiar tesseral form in which H_{cf} is developed in Stevens operator equivalents O_{nm}^α and $\{A_{nm}^\alpha\}$.^{16,18,19} For the sake of consistency, in this article we use only $\{A_{nm}^\alpha\}$ (the relations between $\{A_{nm}^\alpha\}$ and $\{A_k^q\}$ are given in Ref. 16). The final term in Eq. (1) accounts for the interaction of the R magnetic moment with an applied magnetic field; $H_{Zeeman} = -\mu_B(L+2S) \cdot \mu_0 H_{ext}$.

Having chosen a set of CF and exchange parameters, the R^{3+} Hamiltonian can be diagonalized for selected H_{ext} and temperature values to yield the free energy of the R^{3+} ion, $F_R(T)$. Finally, the total energy of the system is

$$E_{Total} = K_1^{Fe} \sin^2 \theta - \langle M_{Fe} \rangle \mu_0 H_{ext} + F_R(T). \quad (3)$$

The magnetic structure of the intermetallic compound may be found by minimizing E_{Total} . Further details of this procedure may be found in Refs. 16, 18, and 19.

The crystal field analysis for 3:29 compounds is complicated by the low symmetry of the monoclinic $Nd_3(Fe,Ti_x)_{29}$ structure. The local point symmetry of the rare earth sites are $2/m$ for $2a$ site and m for $4e$ site, respectively. Hence, there are nine nonvanishing crystal-field parameters for each rare earth site, i.e., eighteen CF parameters in total. The lack of a comprehensive set of magnetization data (e.g., single crystal magnetization measurements) makes the crystal field analysis unmanageable for 3:29 system. However, there is a simple approach to estimate the CF parameters in 3:29, based on a consideration of the structural relationship between the 3:29 structure and the 2:17R and 1:12 structures. In fact, as we have previously shown in our previous article,¹⁷ the local environment of the R ions in the $4e$ site of 3:29 corresponds to that of the $6c$ site in 2:17R, while the $2a$ site in 3:29 corresponds to the $2a$ site in 1:12. Therefore, as a first approximation, we use the crystal field parameters deduced for the R ions in 2:17R (Ref. 20–22) and 1:12 (Ref. 23) as starting parameters for the $4e$ and $2a$ sites in the 3:29 phase. The values of the CF parameters for 2:17R and 1:12 phases are listed in Table I;^{20–23} it should be mentioned that the reported CF parameter values of the 2:17 phase are largely scattered.

In order to consider the three crystallographic structures 3:29, 2:17R, and 1:12, we have chosen the $CaCu_5$ -type (1:5) structure as a reference coordinate system throughout this article since all three of the above structures are ultimately derived from the 1:5 parent structure.¹ It is well known that the c -axis of 2:17R is perpendicular to that of 1:12.¹ There-

FIG. 1. Theoretical magnetization curves for applied field along the c -axis of 1:5 system for (a) $Nd_3(Fe,Ti)_{29}$ and (b) $Sm_3(Fe,Ti)_{29}$. Crystal field coefficients used are listed in Table I and the exchange coefficient used is $n_{RFe} = 285 \pm 5 \mu_0$.

fore, in our calculations we need to transform the CF parameters from 1:12 system to that of 1:5. Using the transformation relationships given by Rudowicz,²⁴ the CF parameters used for our analysis of 3:29 are listed in Table I.

The temperature dependence of the Fe sublattice magnetization and anisotropy of 3:29 phase were determined in our previous magnetization study of $Y_3(Fe,Ti)_{29}$.²⁵ The exchange coefficient n_{RFe} was taken to be $288 \pm 5 \mu_0$. The results of our crystal field calculations are shown in Fig. 1 where the theoretical magnetization curves for $R=Nd$ and Sm are plotted, for an applied field along the c -axis (referring to the underlying 1:5 structure). It can be seen from Fig. 1 that there is a type-II FOMP for both compounds; the calculated critical field values are $\mu_0 H_{cr} = 2.4$ T for $R=Nd$ at 5 K compared to the experimental value of ~ 2 T,⁷ and $\mu_0 H_{cr} = 3.0$ T for $R=Sm$ at 4.2 K compared to ~ 3.2 T found experimentally.⁵ The agreement between the theoretical and experimental values is very good, especially considering the fact that the set of CF coefficients used are virtually identical to those of the corresponding R sites in the 2:17 and 1:12 structures. Our analysis suggests that this magnetic field induced magnetization process is due to the competition between two opposing R-sublattices anisotropies. At the critical field, the magnetization jumps from $\theta = 85^\circ$ to a canted angle of 35° for $R=Nd$ and from 79° to 44° for $R=Sm$, respectively.

Having the CF parameters of the parent 3:29 compounds, it is interesting to investigate the crystal field interactions of their nitrides and carbides. We have previously shown, based on the so-called bonding charge model (BCM), that the shift in A_{20} due to one neighboring N atoms is $\Delta A_{20} = -54 K a_0^{-2}$ for $R_2Fe_{17}N_{3-\delta}$ (Ref. 26) and $-100 K a_0^{-2}$ for $RFe_{11}TiN_{1-\delta}$.²⁷ The number of neighboring inter-

stitial atoms for the fully nitrated compounds is 3 for 2:17 and 2 for 1:12 structures, respectively. Therefore, we have

$$\begin{aligned} A_{20}(4e) &= -25 + (3/4)y(-54) \text{ K } a_0^{-2}, \\ A_{20}(2a) &= +16 + (1/2)y(-100) \text{ K } a_0^{-2} \end{aligned} \quad (4)$$

for the $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_y$ compounds. The values of $A_{20}(4e)$ and $A_{20}(2a)$ deduced from Eq. (4) for the fully nitrated are $A_{20}(4e) = -187 \text{ K } a_0^{-2}$ and $A_{20}(2a) = -184 \text{ K } a_0^{-2}$. Using these leading crystal field coefficients, our calculations show that $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_y$ nitrides become uniaxial anisotropic for $y \geq 2$. We predict a room temperature uniaxial anisotropy field of 11.4 T for the fully nitrated $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_4$ compound which compares well with the experimental values of 10.7 (Ref. 28) to 13 T (Ref. 13). For the 3:29 carbides, the changes in A_{20} are slightly smaller than those of corresponding nitrides.¹⁹ Therefore, the expected anisotropy should be slightly smaller than the value of 11.4 T.

III. CONCLUSION

A quantitative analysis of the available magnetization data on the $R_3(\text{Fe},\text{M})_{29}$ and $R_3(\text{Fe},\text{M})_{29}\text{N}_y$ ($R=\text{Nd},\text{Sm}$) compounds have been carried out. The type-II FOMPs observed in both $\text{Nd}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ and $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}$ are well reproduced with a unique set of crystal-field coefficients. The agreement between the theoretical and experimental critical field values is very good, given that the set of CF coefficients used is virtually identical to those of the corresponding R sites in the 2:17 and 1:12 structures.

Based on the bonding charge model, our calculations show that $R_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_y$ nitrides become uniaxial anisotropic for $y \geq 2$ and a maximum room temperature uniaxial anisotropy field of 11.4 T for the fully nitrated $\text{Sm}_3(\text{Fe}_{1-x}\text{Ti}_x)_{29}\text{N}_4$ compound was predicted, which compares well with the experimental value of 10.7–13 T.

Using Mössbauer spectroscopy and the magneto-optical Kerr effect, we investigate how magnetic order arises and develops in Fe/C and Fe/Cr layered mixtures prepared by pulsed laser deposition. Two different magnetic transformations are found to occur in these systems under their thermal annealing. The first is the paramagnetic-ferromagnetic crossover that takes place at annealing temperatures of 420–570 K in dependence on the average iron content. Varying the latter quantity, we also observed the same crossover to the ferromagnetic state. The second transformation is magnetic hardening at 700–800 K. The specific feature of both transformations is that they occur within narrow ranges of annealing temperature (<10 K). The first transformation is supposed to result from an additional iron enrichment of Fe-rich clusters and is associated with magnetic phase transition near the Curie temperature. The cluster enrichment was directly observed with transmission electron microscopy and was also shown in small angle x-ray scattering patterns of the compositionally modulated structures. The observed sharpening of the magnetic behavior near the Curie temperature is presumably a manifestation of the clustered structure. The second transformation is found to be induced by the onset of crystallization and the formation of particles of the new Fe-rich phase. © 1996 American Institute of Physics. Magnetization processes of free- and fixed-single-crystal antiferromagnets

A simple two-sublattice model is used to analyze the magnetization process of anisotropic antiferromagnets at $T=0$. The magnetization is calculated for samples free to be oriented by the applied field (free single crystals or powders consisting of single-grain particles). We find that the anisotropy does not necessarily lead to a nonlinear $M(B)$ relation, but that the magnetic isotherms are broken into two linear sections separated by a discontinuity. The difference between the slopes in the two regions enables a determination of the anisotropy constant K_1 . The results will be discussed in relation to our findings for the ferrimagnetic case and to the behavior of oriented antiferromagnetic crystals. © 1996 American Institute of Physics. [S0021-8979(96)00108-0]

The study of magnetization processes in two-sublattice systems is mostly conducted with reference to rare-earth—transition-metal compounds. Such compounds are composed of two very dissimilar sublattices. The ferrimagnetic case, with antiferromagnetic intersublattice coupling, is relevant to the compounds formed with heavy-rare-earth elements. These compounds have been studied extensively in recent years because of their relationship to materials used for several technological applications, including permanent magnets, magneto-optical recording, and magnetoelastic transducer devices.

Model calculations of the magnetization processes in two-sublattice ferrimagnets have been based on a phenomenological free-energy expression consisting of the anisotropy energies of both sublattices, the energy of the interaction between the sublattices and the Zeeman energy.¹ Such analyses implicitly include the case of antiferromagnetism, where the anisotropy parameters and the magnetization of the two sublattices are identical. Such parameter values being far removed from those occurring in ferrimagnets of practical interest, this case has received little attention so far. The purpose of the present paper is to reconsider the results on ferrimagnets with this special case in mind and to point out that the magnetization of field-oriented (or free-powder) samples of antiferromagnets with uniaxial sublattice anisotropy show some general features not commonly observed in ferrimagnets. Many of such antiferromagnetic rare-earth compounds have been reported in Ref. 2.

The interest in magnetization curves of field-oriented single-crystalline samples or powders consisting of single-crystal particles arose from the realization that such curves may turn out to be very simple, consisting of three straight sections. The first one of these, stretching to a first critical field B_{cr1} , is horizontal at the value of the spontaneous magnetization $|M_1 - M_2|$. This is followed by a section where the magnetization is proportional to the field, $M = n_{12}^{-1}B$, the slope being equal to the inverse of the intersublattice coupling constant. When the magnetization reaches its saturation value $M_1 + M_2$ at a second critical field B_{cr2} , it becomes again independent of the field. This simple behavior has been shown to prevail in two cases: (1) if at least one of the

sublattices is isotropic and (2) if both sublattices have planar (easy-plane) anisotropies, with no anisotropy in the plane. Clearly, case (1) is irrelevant to anisotropic antiferromagnets and case (2) implies that easy-plane antiferromagnets show the simple magnetization curves known from the ferrimagnet case. Since $M_1 - M_2 = 0$ for antiferromagnets, the first one of the three straight sections described above is absent; the bending of the two sublattice magnetizations towards each other begins at $B_{cr1} = 0$, the linear increase of the magnetization with a slope n_{12}^{-1} stretching to $M = M_1 + M_2$, which is reached at $B_{cr2} = n_{12}(M_1 + M_2)$. This being a very straightforward application of the results known for ferrimagnets, we shall concentrate on antiferromagnets with easy-axis anisotropy in what follows, which will be shown to have some interesting features.

The simplest anisotropic two-sublattice magnets, when they are free to be oriented by the field, can be described by the free energy

$$E = K_1^{(1)} \sin^2 \vartheta_1 + K_1^{(2)} \sin^2 \vartheta_2 + n_{12} M_1 M_2 \cos \alpha - BM, \quad (1)$$

where the first two terms stand for the anisotropy energy, with ϑ_i the angle between the magnetization vector \mathbf{M}_i and the c axis, α is the angle between the magnetization vectors, and M is the magnitude of the total magnetization vector $\mathbf{M} = \mathbf{M}_1 + \mathbf{M}_2$, which is supposed to point into the direction of the applied field \mathbf{B} throughout the magnetization process. It has been shown¹ that the bending of the two magnetization vectors towards each other always takes place within a plane containing the c axis and therefore two angular variables suffice to characterize any state occurring in the process. It turns out that the symmetry properties of an antiferromagnet, $M_1 = M_2 = M_0$ and $K_1^{(1)} = K_1^{(2)} = K_1$, can be best exploited if the free energy is written in terms of $\vartheta = (\vartheta_1 + \vartheta_2)/2$, the angle between the total magnetization vector and the c axis, and $\alpha = \vartheta_2 - \vartheta_1$, the angle between the sublattice magnetizations:

$$E(\vartheta, \alpha) = 2K_1 \left(\sin^2 \vartheta \cos^2 \frac{\alpha}{2} + \cos^2 \vartheta \sin^2 \frac{\alpha}{2} \right) + n_{12} M_0^2 \cos \alpha - 2BM_0 \cos \frac{\alpha}{2}. \quad (2)$$

^{a)}Electronic mail: FRB@Phys.UvA.NL

FIG. 1. (a) Field dependence of the free energy for a free-single-crystal antiferromagnet with easy-axis anisotropy. (b) Field dependence of magnetization. $T=0$ K, $B_{\text{sat}}(0) > B_x$.

To find the minima of the function (2), we first differentiate with respect to ϑ to find

$$\frac{\partial E}{\partial \vartheta} = 2K_1 \sin 2\vartheta \cos \alpha; \quad \frac{\partial^2 E}{\partial \vartheta^2} = 4K_1 \cos 2\vartheta \cos \alpha. \quad (3)$$

The condition $\partial E / \partial \vartheta = 0$ is satisfied at $\alpha = \pi/2$, but this is not a minimum since in this case $\partial^2 E / \partial \vartheta^2$ (as well as all further derivatives) vanishes. The other condition for a vanishing first derivative is $\sin 2\vartheta = 0$. There are two cases of interest, $\vartheta = 0$ and $\vartheta = \pi/2$, where the necessary condition of a minimum, $\partial^2 E / \partial \vartheta^2 > 0$, will be satisfied for $\alpha < \pi/2$ and $\alpha > \pi/2$, respectively. These findings accord with the intuitive notion of uniaxial antiferromagnets: at low fields, where the magnetization vectors are still close to the antiparallel configuration, the $\mathbf{B} \perp c$ ($\vartheta = \pi/2$) configuration is favorable, whereas close to the forced ferromagnetic alignment $\mathbf{B} \parallel c$ ($\vartheta = 0$) gives the lowest anisotropy energy.

Though it is clear that the two conditions found above correspond to two distinct regions, it is instructive to derive the free energy as a function of the magnetic field for both. From Eq. (2) we find for $\vartheta = \pi/2$,

$$E\left(\frac{\pi}{2}, \alpha\right) = 2K_1 \cos^2 \frac{\alpha}{2} + n_{12}M_0^2 \cos \alpha - 2BM_0 \cos \frac{\alpha}{2} \quad (4)$$

and for $\vartheta = 0$,

$$E(0, \alpha) = 2K_1 \sin^2 \frac{\alpha}{2} + n_{12}M_0^2 \cos \alpha - 2BM_0 \cos \frac{\alpha}{2}. \quad (5)$$

The conditions for energy minima, $dE/d\alpha = 0$, give in both cases an explicit expression for $\cos \alpha/2$ ($\sin \alpha/2 \neq 0$) which, substituted back into Eqs. (4) and (5) give the desired functions of the applied field: for $\vartheta = \pi/2$,

$$E\left(\frac{\pi}{2}, B\right) = -n_{12}M_0^2 - \frac{B^2}{2(n_{12} + K_1/M_0^2)} \quad (6)$$

and for $\vartheta = 0$,

$$E(0, B) = 2K_1 - n_{12}M_0^2 - \frac{B^2}{2(n_{12} - K_1/M_0^2)}. \quad (7)$$

Through the relation $M = \partial E / \partial B$ both of these equations imply linearly increasing magnetizations, but this of course cannot prevail beyond saturation where, with $\alpha = 0$, Eqs. (4) and (5) give

$$E_{\text{sat}}\left(\frac{\pi}{2}, B\right) = 2K_1 + n_{12}M_0^2 - 2BM_0, \quad (8)$$

$$E_{\text{sat}}(0, B) = n_{12}M_0^2 - 2BM_0. \quad (9)$$

Equating the respective energies given by Eqs. (6), (7) and by Eqs. (8) and (9) gives the field values where saturation sets in. In both cases we find only one such value,

$$B_{\text{sat}}\left(\vartheta = \frac{\pi}{2}\right) = 2M_0\left(n_{12} + \frac{K_1}{M_0^2}\right), \quad (10)$$

$$B_{\text{sat}}(\vartheta = 0) = 2M_0\left(n_{12} - \frac{K_1}{M_0^2}\right). \quad (11)$$

indicating that the straight lines given by Eqs. (8) and (9) are tangent to the parabolae (6) and (7), as illustrated by Fig. 1(a).

Having constructed the free-energy curves, it is now easy to identify the lowest-energy track, which will be followed in the magnetization process. Clearly, up to $B = B_x$, where the two parabolae cross, $\vartheta = \pi/2$ and beyond this field $\vartheta = 0$. Setting the energies given by Eqs. (6) and (7) equal, we find

$$B_x^2 = 2M_0^2\left[n_{12}^2 - \left(\frac{K_1}{M_0^2}\right)^2\right]; \quad (3K_1 \leq M_0^2 n_{12}). \quad (12)$$

The condition satisfied by this equation will be discussed below. The slopes of the two curves being different at B_x , there must be a discontinuity in the magnetization,

FIG. 2. (a) Field dependence of the free energy for a free-single-crystal antiferromagnet with easy-axis anisotropy. (b) Field dependence of magnetization. $T=0$ K, $B_{\text{sat}}(0) < B_x$.

FIG. 3. Field dependence of the free energy and magnetization for a fixed single-crystal antiferromagnet with easy-axis anisotropy. (a) The applied field is along the hard-magnetization direction. (b) The applied field is along the easy-magnetization direction.

$$\Delta M = 2\sqrt{2}M_0 \sqrt{(K_1/M_0^2)^2/[n_{12}^2 - (K_1/M_0^2)^2]}. \quad (13)$$

Figure 1(b) shows the magnetization curve derived from the solid free-energy curve in Fig. 1(a). The magnetization will jump directly to its saturation value whenever $B_{\text{sat}}(\vartheta=0) < B_x$. Using Eqs. (11) and (12), we find that this will be the case when $3K_1 > n_{12}M_0^2$. Under this condition, Eq. (12) has to be replaced by the expression found after equating the energies given by Eqs. (6) and (9)

$$B_x = 2M_0(n_{12} + K_1M_0^2)(1 - \sqrt{K_1/[n_{12}M_0^2 + K_1]}), \quad (14)$$

$$3K_1 \geq n_{12}M_0^2.$$

Figure 2 shows the free-energy and magnetization curves for such a case.

The linear behavior of the magnetization seen in Figs. 1 and 2 is a consequence of the simple form of the anisotropy energy assumed in Eq. (1). However, the occurrence of a jump in the magnetization is a general feature of easy-axis antiferromagnets, as can be seen from the following argument.

Replacing the lowest-order expression $K_1 \sin^2 \vartheta$ by a more general form $E_{\text{an}}(\vartheta)$ of the sublattice anisotropy energy will not prevent the crossing of the $E(\pi/2, B)$ and $E(0, B)$ curves. Since $E_{\text{an}}(0) < E_{\text{an}}(\pi/2)$ must hold to ensure easy-axis anisotropy, it follows that $E(\pi/2, 0) - E(\vartheta, 0) = 2[E_{\text{an}}(0) - E_{\text{an}}(\pi/2)] < 0$, whereas at saturation (in the

forced ferromagnetic state) $E_{\text{sat}}(\pi/2, B) - E_{\text{sat}}(0, B) = 2[E_{\text{an}}(\pi/2) - E_{\text{an}}(0)] > 0$. The form of the function $E_{\text{an}}(\vartheta)$ is thus seen to influence the shape of the curved parts of the free-energy functions, but the order of the energy values at zero field and high fields ($B > B_{\text{sat}}$) will remain inverted, making an intercept with different slopes and hence a jump in the magnetization inevitable.

The discontinuity in the magnetization is reminiscent of first-order phase transitions, but it should be born in mind that this transition is related to the additional degrees of freedom introduced by the free rotation of the crystals. Indeed, switching from the $\vartheta = \pi/2$ curve to the $\vartheta = 0$ one in Figs. 1 and 2 signifies a rotation of the sample by 90° . The discontinuous changes (spin-flop transitions) known to occur in oriented antiferromagnets are of a different nature. Preliminary experimental results have been reported in Ref. 3.

The free-energy functions (6)–(9) are relevant to the magnetization process in samples fixed at $\mathbf{B} \perp c$ and $\mathbf{B} \parallel c$ orientations. If $\mathbf{B} \perp c$, the bending process traces the $E(\pi/2, B)$ curve to $B_{\text{sat}}(\vartheta = \pi/2)$ and the $E_{\text{sat}}(\pi/2, B)$ line thereafter. The magnetization increases continuously up to saturation [Fig. 3(a)]. If $\mathbf{B} \parallel c$, bending does not begin at $B = 0$, because in weak fields the Zeeman energy cannot overcome the anisotropy. The sublattice magnetizations remain in the c direction, fully compensated ($M = 0$), until the point is reached (at B_f), where the $E(0, B)$ curve falls below $E(\pi/2, 0)$ [Fig. 3(b)]. The transition taking place at this point is not necessarily to a state with $\alpha < \pi/2$, which is one of the features distinguishing it from what takes place in freely rotating samples. Another related feature is the distinct value of B_f , which follows from the condition $E(\pi/2, 0) = E(0, B_f)$: $B_f^2 = 4K_1(n_{12} - K_1/M_0^2)$, provided $2K_1 \leq n_{12}M_0^2$. The limitation of K_1 to low values comes from the requirement that B_f be less than $B_{\text{sat}}(\vartheta = 0)$. If that is not the case, the spin-flop will be total, leading to saturation, and B_f is to be determined from the condition $E(\pi/2, 0) = E_{\text{sat}}(0, B_f)$, which gives $B_f = n_{12}M_0$, provided $2K_1 \geq n_{12}M_0^2$. Comparing these results with Eqs. (12) and (14) it clear that B_x and B_f mark the occurrence of transitions of different nature.

Dynamics of quantum spin systems in dimer and valence-bond-solid ground states stabilized by competing interactions

Yongmin Yu and Gerhard Müller

Department of Physics, The University of Rhode Island, Kingston, Rhode Island 02881-0817

For special coupling ratios, the one-dimensional (1D) $s=1/2$ Heisenberg model with antiferromagnetic nearest and next-nearest neighbor interactions has a pure dimer ground state, and the 1D $s=1$ Heisenberg model with antiferromagnetic bilinear and biquadratic interactions has an exact valence-bond-solid ground state. The recursion method is used to calculate the $T=0$ spin dynamic structure factor for both models and, for the $s=1/2$ model, also the dimer dynamic structure factor. New results for line shapes and dynamically relevant dispersions are obtained.

© 1996 American Institute of Physics. [S0021-8979(96)00208-7]

Correlated quantum fluctuations in the ground state are a generic feature of quantum many-body systems. They make it hard to take finite-size effects into account in computational studies of zero-temperature dynamical properties. Interestingly, there are several known cases, where a relatively simple-structured ground state is stabilized by competing terms in the microscopic Hamiltonian. This ground state may or may not be long-range ordered. The essential attribute is that its fluctuations are not correlated or only over a short distance on the lattice. This phenomenon typically occurs with no accompanying simplification in the excitation spectrum or any dynamical quantity. Nevertheless, any such situation provides an unsuspected window for dynamical studies which promise to be much less plagued with finite-size effects than is typically the case. The recursion method¹ in combination with recently developed techniques of continued-fraction analysis² is an ideal calculational tool for that purpose, the key property being that it extracts the dynamical information from the ground-state wave function.

In a previous paper we have reported the study of one such case, namely the one-dimensional (1D) spin- s XYZ model.³ In a magnetic field of particular strength, this model has a product ground state with spontaneous ferro- or antiferromagnetic long-range order perpendicular to the field. Here we present new results for two different models with simple-structured ground states.

The first model is the 1D $s=1/2$ Heisenberg antiferromagnet with competing nearest and next-nearest neighbor interactions,

$$H = \sum_{l=1}^N \{J_1 \mathbf{S}_l \cdot \mathbf{S}_{l+1} + J_2 \mathbf{S}_l \cdot \mathbf{S}_{l+2}\}, \quad (1)$$

with an even number of spins and periodic boundary conditions. This system undergoes a $T=0$ phase transition at $J_2/J_1 \approx 0.25$ from a spin-fluid phase to a phase with spontaneous dimer long-range order.⁴ In the (critical) spin-fluid phase, the correlations of the quantum fluctuations are particularly strong. In the dimer phase, their continued presence, albeit much attenuated, manifests itself, for example, in the finite-size splitting of the ground-state doublet. The exception is the special coupling ratio $J_2/J_1 = 0.5$, where the pure dimer ground-state is realized.^{5,6} Here the ground-state energy per site is size-independent: $E_0/N = -\frac{3}{8}J_1$.

The two (translationally invariant) dimer ground-state wave functions can be expressed in terms of products of singlets formed by pairs of nearest neighbor spins:

$$|\Phi_{\pm}\rangle = [2 \pm (-1/2)^{(N-4)/2}]^{-1/2} \{|\Phi_1\rangle \pm |\Phi_2\rangle\}, \quad (2)$$

where $|\Phi_1\rangle = [1,2][3,4] \dots [N-1,N]$, $|\Phi_2\rangle = [2,3][4,5] \dots [N,1]$, $\times [l, l+1] = \{|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle\}/\sqrt{2}$.

The dimer order parameter, $D = N^{-1} \sum_l (-1)^l D_l$, $D_l = S_l^+ S_{l+1}^- + S_l^- S_{l+1}^+$, has a nonzero expectation value, $\langle D \rangle = \pm 1/2$ in the (non-orthogonal) symmetry-breaking states $|\Phi_1\rangle$ and $|\Phi_2\rangle$. The order-parameter correlation function in this case is not a two-spin correlation function, ($\langle S_l^z S_{l+n}^z \rangle = 0$ for $|n| > 1$), but a four-spin correlation function: $\langle D_l D_{l+n} \rangle - \langle D_l \rangle \langle D_{l+n} \rangle = (-1)^n/4$ for $n \neq 0$. Hence it will be instructive to compare the spin dynamic structure factor $S_{zz}(q, \omega)$ and the dimer dynamic structure factor $S_{DD}(q, \omega)$, i.e. the function

$$S_{AA}(q, \omega) = \int_{-\infty}^{+\infty} dt e^{i\omega t} \langle A_q(t) A_{-q} \rangle, \quad (3)$$

where A_q stands for the spin fluctuation operator, $S_q^z = N^{-1/2} \sum_l e^{iql} S_l^z$ or the dimer fluctuation operator, $D_q = N^{-1/2} \sum_l e^{iql} [D_l - \langle D_l \rangle]$.

By means of the recursion method¹ in combination with a strong-coupling continued-fraction analysis,^{2,7} we calculate the dynamically relevant excitation spectra and the spectral-weight distributions of these two functions. The recursion algorithm in the present context is based on an orthogonal expansion of the wave function $|\Psi_q^A(t)\rangle = A_q(-t)|\Phi\rangle$. It produces (after some intermediate steps) a sequence of continued-fraction coefficients $\Delta_1^A(q), \Delta_2^A(q), \dots$ for the relaxation function,

$$c_0^{AA}(q, z) = \frac{1}{z + \frac{\Delta_1^A(q)}{z + \frac{\Delta_2^A(q)}{z + \dots}}}, \quad (4)$$

which is the Laplace transform of the symmetrized correlation function $\Re \langle A_q(t) A_{-q} \rangle / \langle A_q A_{-q} \rangle$. The $T=0$ dynamic structure factor (3) is then obtained from (4) via

$$S_{AA}(q, \omega) = 4 \langle A_q A_{-q} \rangle \Theta(\omega) \lim_{\varepsilon \rightarrow 0} \Re [c_0^{AA}(q, \varepsilon - i\omega)]. \quad (5)$$

FIG. 1. Dynamic structure factor $S_{zz}(q, \omega)$ vs ω for $q=2\pi l/N$, $l=0, 1, \dots, N/2$ in the dimer ground state $|\Phi_+\rangle$ of the Hamiltonian (1) at $J_2=0.5$ and $J_1=1$ with $N=18$, obtained via strong-coupling continued-fraction reconstruction based on the coefficients $\Delta_1, \dots, \Delta_9$ and a Gaussian terminator as explained in Refs. 2 and 7.

The simple N -dependence of the dimer ground-state wave functions (2) offers the advantage that we can compute a significant number of N -independent coefficients $\Delta_k^A(q)$. These data are the input to the well-tested strong-coupling continued-fraction reconstruction.^{2,7}

The results for the frequency-dependence of the dynamic structure factor $S_{zz}(q, \omega)$ at the wave numbers realized for $N=18$ are displayed in Fig. 1. The set of curves is perfectly compatible with a function $S_{zz}(q, \omega)$ that varies smoothly in q as well as in ω . For every q -value we observe a single peak in the frequency range of interest. This peak is very broad at q near zero or π . The width shrinks as q approaches $\pi/2$ from either side.

At $q = \pi/2$ (not realized for $N=18$) the dynamically relevant excitation spectrum reduces to a single mode. The states $S_{\pi/2}^z |\Phi_{\pm}\rangle$ are, in fact, known to be exact eigenstates of the system.^{8,9} The dynamically relevant dispersion of $S_{zz}(q, \omega)$ is symmetric about $q = \pi/2$, where it has a smooth maximum at frequency $\omega/J_1 = 1.0$. For $q=0$ and $q=\pi$ it has smooth minima at $\omega/J_1 \approx 0.5$.

On the basis of a variational calculation for the pure dimer state, Shastry and Sutherland⁶ obtained an excitation spectrum for this model which consists of a continuum of two-defect scattering states with a lower boundary $\epsilon(q) = J_1(\frac{5}{4} - |\cos q|)$ and, for the restricted range $0.36\pi < q < 0.64\pi$ of wave numbers, a branch of defect bound states, which emerges from the lower continuum boundary and has a smooth maximum reaching up to $\omega/J_1 = 1$ at $q = \pi/2$.

In this context, our results suggest that for q near zero or π , the spectral weight of $S_{zz}(q, \omega)$ is distributed over a broad frequency range of two-defect scattering states. As q approaches $\pi/2$ from either side, the spectral weight is shifted gradually to the two-defect bound state.

Our result for the dynamic structure factor $S_{DD}(q, \omega)$ is plotted in Fig. 2 for the same set of wave numbers. The line shapes and peak positions resemble those shown in Fig. 1 for

FIG. 2. Dynamic structure factor $S_{DD}(q, \omega)$ vs ω for $q=2\pi l/N$, $l=0, 1, \dots, N/2$ in the dimer ground state $|\Phi_+\rangle$ of the Hamiltonian (1) at $J_2=0.5$ and $J_1=1$ with $N=18$, obtained via strong-coupling continued-fraction reconstruction based on the coefficients $\Delta_1, \dots, \Delta_9$ and a Gaussian terminator.

$S_{zz}(q, \omega)$, but there are some notable differences: The spectral weight in $S_{DD}(q, \omega)$ is concentrated at somewhat higher energies. The intensity at $q=0$ is nonzero. The shape of the dimer dispersion is different. $S_{DD}(\pi/2, \omega)$ does not reduce to a single line. In $S_{DD}(\pi, \omega)$ the spectral weight is shared between a continuum and a δ -peak at $\omega=0$. The latter contribution reflects the presence of dimer long-range order in the ground state.

The Hamiltonian of the 1D $s=1$ model with isotropic bilinear and biquadratic exchange, our second example, is most conveniently expressed in the form

$$H_\gamma = J \sum_{l=1}^N \{ \cos \gamma \mathbf{S}_l \cdot \mathbf{S}_{l+1} + \sin \gamma (\mathbf{S}_l \cdot \mathbf{S}_{l+1})^2 \} \quad (6)$$

with a single parameter $-\pi < \gamma \leq \pi$. More than a decade of research on this model has established a $T=0$ phase diagram consisting of the short-range ordered Haldane phase and three phases with dimer, trimer, and ferromagnetic long-range order.¹⁰ In the Haldane phase, which includes the Heisenberg antiferromagnet ($\gamma=0$), the ground state is a non-degenerate singlet state ($S_T=0$) separated by a gap from the threshold of the excitation spectrum.

At the parameter value $\gamma = \arctan(1/3) \approx 18.4^\circ$ within this phase, the ground-state wave function is exactly known.¹¹ It is a realization of the so-called valence-bond-solid (VBS) wave function, which can be assembled from the same parts as the dimer state (2). The spin 1 at each lattice site is expressed as a spin-1/2 pair in a triplet state. The singlet-pair forming valence bond involves one fictitious spin 1/2 from each of two neighboring lattice sites. The VBS state can then be regarded as a chain of valence bonds linking successive symmetrized spin-1/2 pairs, which are given by the $S_T^z=0$ vector of the triplet on each lattice site.

The static spin correlation function in the VBS state,¹¹ $\langle S_l^z S_{l+n}^z \rangle = \frac{4}{3}(-1)^n 3^{-|n|}$, ($n \neq 0$), reflects magnetic short-range order with a very short correlation length:

FIG. 3. Dynamic structure factor $S_{zz}(q, \omega)$ vs ω for $q = 2\pi l/N$, $l = 0, 1, \dots, N/2$ in the VBS ground state of the model system (6) at $J = 1$ and $\gamma = \arctan(1/3)$ with $N = 12$, obtained via a strong-coupling continued-fraction analysis based on the coefficients $\Delta_1, \dots, \Delta_6$ and a Gaussian terminator.

$\xi = 1/\ln 3 \approx 0.91$. The static structure factor is then a non-singular function with a smooth minimum at $q = 0$ and a smooth maximum at $q = \pi$:

$$S^{zz}(q) = 2(1 - \cos q)/(5 + 3 \cos q). \quad (7)$$

The simple structure of the VBS state makes this quantity free of finite-size effects for $q = 2\pi l/N$, $l = 0, \dots, N-1$. Again, this simplification does not extend to the excitation spectrum and the dynamical properties.

In Fig. 3 we have plotted $S_{zz}(q, \omega)$ as obtained from a strong-coupling continued-fraction analysis with coefficients extracted from the $N = 12$ VBS wave function. At each value of q the spectral weight of $S_{zz}(q, \omega)$ is found to be concentrated in a single peak with symmetric line shape. The peak frequency decreases monotonically with q . The suggested

gap value at $q = \pi$ is $\Delta E/J \approx 0.66$, in good agreement with the result $\Delta E/J \approx 0.70$ of the single-mode approximation.¹² The linewidth tends to be very small at q near π , where the peak frequency is lowest and the intensity highest. It gains considerably in breadth at q near 0, where the peak frequency is higher and the intensity much lower.

The monotonic q -dependence of the dynamically relevant dispersion for $S_{zz}(q, \omega)$ in the VBS state ($\gamma \approx 18.4^\circ$) is markedly different from the corresponding quantity in the Heisenberg antiferromagnet ($\gamma = 0$), which belongs to the same phase. In the Heisenberg case, the dispersion has a smooth maximum at $q \approx \pi/2$ and smooth minima of unequal height at $q = 0$ and $q = \pi$.¹³

The decay of (disorder-averaged) static spin correlation functions at $T=0$ for the one-dimensional spin-1/2 XXZ antiferromagnet with uniform longitudinal coupling $J\Delta$ and random transverse coupling $J\lambda_i$ is investigated by numerical calculations for ensembles of finite chains. At $\Delta=0$ (XX model) the calculation is based on the Jordan-Wigner mapping to free lattice fermions for chains with up to $N=100$ sites. At $\Delta \neq 0$ Lanczos diagonalizations are carried out for chains with up to $N=22$ sites. The longitudinal correlation function $\langle S_0^z S_r^z \rangle$ is found to exhibit a power-law decay with an exponent that varies with Δ and, for nonzero Δ , also with the width of the λ_i -distribution. The results for the transverse correlation function $\langle S_0^x S_r^x \rangle$ show a crossover from power-law decay to exponential decay as the exchange disorder is turned on. © 1996 American Institute of Physics. [S0021-8979(96)00308-3]

The combination of randomness and quantum fluctuations is well known to be a fertile ground for interesting physical phenomena including Anderson localization. In one-dimensional (1D) tight-binding systems the rule is that disorder always leads to localization. However, if the randomness is purely off-diagonal, the localization length diverges at the band center,¹ which is bound to affect the decay law of correlation functions. One particular off-diagonally disordered fermion model, the 1D half-filled tight-binding model with random hopping, is equivalent to the special XX case ($\Delta=0$) of the 1D $s=1/2$ XXZ model with random transverse exchange coupling, described by the Hamiltonian

$$H = J \sum_i [\lambda_i (S_i^x S_{i+1}^x + S_i^y S_{i+1}^y) + \Delta S_i^z S_{i+1}^z]. \quad (1)$$

The uniform longitudinal spin coupling corresponds to a fermion interaction. Here we consider the range $0 \leq \Delta \leq 1$, use periodic boundary conditions, and take the random transverse coupling $J\lambda_i$ to be described by a Gaussian distribution with $\overline{\lambda_i} = 1$, $\overline{\lambda_i \lambda_j} = 1 + \sigma^2 \delta_{ij}$. The spin correlations at $T=0$ of this model were recently investigated by means of a real-space renormalization group (RSRG) method^{2,3} based in part on ideas from earlier work,⁴ and by means of a finite-chain study.⁵

One interesting proposition made in the context of the RSRG study is the existence of a *random-singlet phase* with algebraically decaying spin pair correlations:^{2,3}

$$\langle S_0^\alpha S_r^\alpha \rangle \sim (-1)^r r^{-\eta_\alpha}, \quad \alpha = x, z. \quad (2)$$

The singlet nature of that phase would imply that the characteristic exponent η_α assumes the same value in the longitudinal (z) and transverse (x) correlation functions, in marked contrast to the case with no exchange disorder ($\sigma=0$), for which we know the exact result⁶

$$\eta_x = 1/\eta_z = 1 - (1/\pi) \arccos \Delta. \quad (3)$$

The RSRG study further predicts that this exponent value is $\eta_x = \eta_z = 2$, independent of the longitudinal coupling Δ and the disorder strength σ , provided the latter is not too small. It is indeed quite unusual that the anisotropic randomization of an anisotropic exchange interaction should effectively remove the effects of anisotropy in the spin correlations.

Here we report results of a finite-chain study which goes significantly beyond that of Ref. 5 in statistics and system sizes. For the XX model ($\Delta=0$), we carry out the computation in the (free-) fermion representation, which enables us to handle chains with up to $N=100$ spins and beyond. For $\Delta \neq 0$ we must resort to Lanczos diagonalizations. Here the largest system for which we can perform the computation with reasonable statistics has $N=22$ sites. For graphical purposes we shall consider, henceforth, the absolute value, $|\langle S_0^\alpha S_r^\alpha \rangle|$, of the spin pair correlations.

We first consider the case $\Delta=0$ (XX model). If the longitudinal correlation function does exhibit power-law decay, $|\langle S_0^z S_r^z \rangle| \sim r^{-\eta_z}$, as predicted, then the exponent η_z also governs the N -dependence of the function $|\langle S_0^z S_{N/2}^z \rangle|$ in a cyclic chain of N sites.⁵ We have evaluated this quantity for systems with $N \leq 100$ sites and for disorder strengths $\sigma \leq 2$, all with ensemble averages over up to 10^5 configurations.

The data analysis yields $\eta_z = 2$ independent of σ . This is consistent with the RSRG prediction^{2,3} but in contradiction to the earlier finite-size study,⁵ where a significant σ -dependence of η_z was observed.⁷ Our data also confirm that the disorder-averaged logarithm of $|\langle S_0^z S_r^z \rangle|$ exhibits the decay law $\sim -r^{1/2}$ as predicted in Ref. 3.

The decay of the transverse correlation function $\langle S_0^x S_r^x \rangle$ is much more sensitive to the presence of exchange disorder, as is demonstrated by the data shown in Figs. 1 and 2. In the main diagram of Fig. 1 we show the function $|\langle S_0^x S_r^x \rangle|$ versus r in a logarithmic plot for ensembles with different disorder strengths. Turning on the exchange disorder with gradually

FIG. 1. Log-log plot of $|\langle S_0^x S_r^x \rangle|$ at $T=0$ in the random-exchange XX chain ($\Delta=0$) with $N=40$ spins at disorder strengths $\sigma=0, 0.1, \dots, 1$ (top to bottom). For $0 < \sigma \leq 0.5$ the expectation value of $\langle S_0^x S_r^x \rangle$ has been averaged over 10^4 configurations, and for $\sigma > 0.5$, over 10^5 configurations. The inset shows the (effective) decay exponent η_x as a function of the disorder strength σ .

increasing σ causes the transverse correlations to decay more and more rapidly as one might expect.⁸

For $0 \leq \sigma \leq 0.5$ the data describe a power-law behavior. This is also evident in the bundle of curves near the top of Fig. 2, which shows the r -dependence of the function $|\langle S_0^x S_r^x \rangle|$ semi-logarithmically at $\sigma=0.4$ for various system sizes. The values $|\langle S_0^x S_{N/2}^x \rangle|$ at the endpoints of these curves plotted vs $N/2$ in a log-log graph fall onto a straight line, and the slope of that line determines the exponent η_x . This is illustrated by the full squares in the inset to Fig. 2.

The σ -dependence of η_x as obtained from this procedure is shown in the inset to Fig. 1. For the system without exchange disorder we reproduce the exactly known value $\eta_x = 1/2$,⁹ which is a special case of (3). As σ increases from zero, η_x grows gradually and monotonically, at first slowly, then more and more rapidly.

For $\sigma \geq 0.5$ the curves in Fig. 1 suggest the occurrence of a crossover from algebraic decay to exponential decay, $|\langle S_0^x S_r^x \rangle| \sim \exp(-r/\xi)$, in the range of r for which we have data. The exponential character of the decay is more strikingly manifest in the lower bundle of data shown in the main plot of Fig. 2, representing the function $|\langle S_0^x S_r^x \rangle|$ at $\sigma=1$ for various system sizes.⁸ The smallest expectation values are known only with considerable (relative) uncertainty despite the augmented statistics.

The triangles, which represent the values $|\langle S_0^x S_{N/2}^x \rangle|$ vs $N/2$ in this semi-logarithmic plot, are consistent with a straight line. Its slope determines the disorder-induced correlation length ξ . Over the range of disorder strengths, where our data suggest exponential decay of $|\langle S_0^x S_r^x \rangle|$, ξ thus determined decreases monotonically with increasing σ .

Our data for the exchange disordered XX model are con-

FIG. 2. Semi-logarithmic plot of $|\langle S_0^x S_r^x \rangle|$ with $r \leq N/2$ at $T=0$ in the random-exchange XX chain ($\Delta=0$) with $N = 18, 22, 26, 30, 34, 40$, for $\sigma=0.4$ (upper set of curves, averaged over 10^4 configurations) and $\sigma=1$ (lower set of curves, averaged over 10^5 configurations). The data points for $\sigma=1$ at maximum distance ($r=N/2$) are marked by full triangles. The straight line which best fits these data points is shown dot-dashed and determines the correlation length ξ . The inset shows the data for $\sigma=0.4$ in a log-log plot. The data points at maximum distance ($r=N/2$) are marked by full squares. The straight line which best fits these data points is shown dot-dashed and determines the correlation exponent η_x .

sistent with two alternative scenarios, which are equally interesting:

- (i) There exists a transition at some nonzero value of the disorder strength, $\sigma_c \approx 0.5$, from algebraically to exponentially decaying transverse spin correlations.
- (ii) A transition of the same nature occurs at $\sigma_c = 0$ instead, which produces very similar crossover effects in the finite-chain data.

A more extensive study for longer chains and with better statistics will be necessary to discriminate with confidence between the two scenarios.¹⁰ The data are definitely incompatible with a persistent power-law decay as predicted by RSRG.

Now we turn to one case, $\Delta=0.75$, with fermion interaction (XXZ model). Since the computations are much more involved, the available data are limited by comparison with the case $\Delta=0$. At $\Delta \neq 0$ neither our data for the longitudinal correlations nor those for the transverse correlations are compatible with the RSRG predictions.

The function $|\langle S_0^z S_r^z \rangle|$ for various system sizes and $\sigma=1.5$ is shown logarithmically in Fig. 3. The endpoint data ($r=N/2$), which fall neatly onto a straight line, describe a power-law decay with $\eta_z=1.26$. The exponent values obtained for two smaller disorder strengths are $\eta_z=1.17$ ($\sigma=0.5$) and $\eta_z=1.31$ ($\sigma=0.25$). The exact result (3) for $\sigma=0$ assumes the value $\eta_z=1.298 \dots$

All combined, the data suggest that the function $|\langle S_0^z S_r^z \rangle|$ is governed by a power-law which persists in the presence of randomness. The σ -dependence of the exponent

FIG. 3. Log-log plot of $|\langle S_0^x S_r^x \rangle|$ for the XXZ model with uniform longitudinal exchange ($\Delta=0.75$) and random transverse exchange ($\sigma=1.5$) on chains of various lengths. The data points represent averages over 1000 configurations for $N=6, \dots, 18$, and 450 configurations for $N=22$.

η_z appears to go through a minimum of considerable depth at $\sigma \neq 0$,¹¹ which implies the curious phenomenon that the longitudinal correlations are enhanced by a small amount of transverse exchange disorder relative to the correlations in the uniform-exchange system.

The data for the transverse correlations $|\langle S_0^x S_r^x \rangle|$ at $\Delta=0.75$ exhibit properties very similar to what we have observed and described for the free-fermion case ($\Delta=0$). For not too large disorder strengths ($\sigma \lesssim 0.5$), we see a power-law behavior with an exponent that increases monotonically from the exactly known value $\eta_x=0.769\dots$ at $\sigma=0$, as given by expression (3), to $\eta_x=1.00$ at $\sigma=0.25$ and $\eta_x=1.49$ at $\sigma=0.5$, at which point a crossover to exponential behavior makes itself felt. The exponential decay law at $\sigma=1.5$ is quite evident in the semi-logarithmic plot of Fig. 4.

The discrepancies between our results and the RSRG predictions of Refs. 2,3 call for an explanation in future studies. Possibly, the strongly *anisotropic* nature of the exchange in the model system (1) – even for $\Delta=1$ – is not adequately taken into account by the RSRG procedure, which derives from a method originally developed for a model with *isotropic* exchange.⁴

In order to gain further insight into the properties of the XXZ chain with random exchange, we plan to investigate the

FIG. 4. Semi-logarithmic plot of $|\langle S_0^x S_r^x \rangle|$ for the XXZ model with uniform longitudinal exchange ($\Delta=0.75$) and random transverse exchange ($\sigma=1.5$) on chains of various lengths. The data points represent averages over 1000 configurations for $N=6, \dots, 18$, and 450 configurations for $N=22$.

nature of low-lying excitations and the properties of dynamic correlation functions. At $\Delta=0$ the Jordan-Wigner mapping to free fermions will make it possible to carry out these calculations for large systems. At $\Delta \neq 0$ the KPM method developed recently¹² promises to be an adequate calculational instrument.

Rotational hysteresis and self-organized criticality in magnetic recording media

T. L. Templeton and A. S. Arrott

Physics Department, Simon Fraser University, Burnaby, British Columbia, V5A 1S6, Canada

Collective magnetic dipoles are written into sections of commercial magnetic recording tapes by application of high fields at angles θ_{set} with respect to the tape axis. The media is rotated 2000 times about the tape normal in a lower magnetic field H_m in the plane of the tape. The magnetization along the direction of H_m is measured in steps of $\Delta\theta = \pi/5$. Harmonic analysis of the angular dependence of the magnetization is used to discover how the dipole term depends on cycle number n , H_m , the direction of rotation, and θ_{set} . The data are analyzed using $\mu_d(n) = \mu_d(\infty) + [\mu_d(1) - \mu_d(\infty)]n^{-\gamma}$. This dipole disappears on rotation for an infinite number of cycles in fields $H_m > H_{\text{crit}}$. For $H_m < H_{\text{crit}}$, $\mu_d(\infty)$ depends on H_m much as $M_s(T)$ depends on temperature. For H_m close to H_{crit} , γ becomes as small as 0.1 for which 10^{10} cycles would be required to produce 90% of the change.

© 1996 American Institute of Physics. [S0021-8979(96)04108-8]

The purpose of this paper is to call the attention of theorists interested in self-organized criticality¹ to a system that is more amenable to both numerical simulations and experimental realization than several previously studied phenomena.²⁻⁵ The object of our studies is a previously magnetized piece of magnetic recording tape in which, during rotation by 360° in a field H_m of the order of the coercivity, some of the particles switch the direction of magnetization and some of them do not. Which particles switch depends on the field and on past history. For rotation through many cycles, an equilibrium should be approached in which a fraction $f_{+\infty}$ remains magnetized in the original direction, another fraction $f_{-\infty}$ remains magnetized in the opposite direction, and the rest $f_{S\infty} = 1 - f_{+\infty} - f_{-\infty}$ switch twice on each cycle or some small set of cycles. We can not measure directly these fractions because there are angular distributions of the magnetic moments. These come from the spatial dispersion of the axes of the particles, the effect of the applied field on the direction of the moment, and the effects of dipole-dipole interactions. We measure the magnetic moment along the field direction at 10 angles during a rotation through 360° for up to 2000 cycles. We analyze the response in each cycle into its harmonic components. From the component that goes as

$$\mu_d(\theta, n) = \mu'_d(n) \cos(\theta) + \mu''_d(n) \sin(\theta), \quad (1)$$

we extract the net dipole in the n th cycle,

$$\mu_d(n) = \sqrt{[\mu'_d(n)]^2 + [\mu''_d(n)]^2}, \quad (2)$$

and its angle

$$\beta_d(n) = \arctan[\mu''_d(n)/\mu'_d(n)]. \quad (3)$$

We normalize these moments to the moment μ_s measured at saturation, $\mu_0 H_s = 1.2$ T. (Because the dipole changes more in the first half than the second half of a cycle there is some ambiguity about the meaning of n ; we use $n = p + 1/2$ for the p th cycle.) This is repeated for up to 20 different fields and for both clockwise, cw, and counter clockwise, ccw, rotations.

In the limit of an infinite number of cycles, $\mu_d(\infty)$ should be finite below some critical field H_{crit} and zero above. We fit the dependence of $\mu_d(n)$ on the cycle number using the three parameter expression

$$\mu_d(n) = \mu_d(\infty) + [\mu_d(1) - \mu_d(\infty)]n^{-\gamma}, \quad (4)$$

where $\mu_d(\infty)$ and $\mu_d(1)$ are parameters rather than direct measurements and therefore depend on the choice of the power γ . The data for the first two cycles are not used. From our measurements we determine the dependence of the three parameters $\mu_d(\infty)$, $\mu_d(1)$, and γ on the measuring field for fields from zero to saturation. This is done for various directions of the initial dipole with respect to the tape axis; that is, the initial saturating field is applied at an angle θ_{set} . The cycles are started from the direction of θ_{set} . The range of θ_{set} from 0 to 90° should be sufficient, but we carry out measurements for θ_{set} from 0 to 144° to be sure. The angles of most interest are $\theta_{\text{set}} = 0, 81^\circ$, and 90° . The analysis here differs from that given previously in that the order of extrapolation and harmonic analysis are reversed.⁶ It is reassuring that the order does not matter.

The experiments have been carried out using four basic types of magnetic recording tapes. The data reported here are for a "FUJI FR metal" tape. There are time effects that cannot be ignored for CrO_2 tapes and which are troublesome for $\gamma\text{-Fe}_2\text{O}_3$ based tapes, whereas for the metallic tapes they are barely detectable. The study of time effects will be reported separately.

Equation (4) is empirical, based on the ubiquitous presence of power laws throughout the physical world. Three parameters is the minimum number required by the data shown on the left in Fig. 1 for $\theta_{\text{set}} = 0, 81^\circ$, and 90° and for measuring fields $\mu_0 H_m = 0.073, 0.081, 0.094, 0.104$, and 0.119 T. Here we plot $\Delta\mu_d \equiv [\mu_d(n) - \mu_d(\infty)]/[\mu_d(1) - \mu_d(\infty)] = n^{-\gamma}$. The solid line curve fits are generated from Eq. (4) which requires that $\Delta\mu_d = 1$ at $n = 1$ and $\Delta\mu_d = 0$ at $n = \infty$. It should be noted that the decay is slowest for H_m just below the coercivity H_c , as discussed previously.⁶ For $\gamma = 0.1$, the extrapolation from $n = 2000$ spans one half of the change. The normalization to $\mu_d(1) - \mu_d(\infty)$ accentuates the error bars for the results at the higher and lower fields where

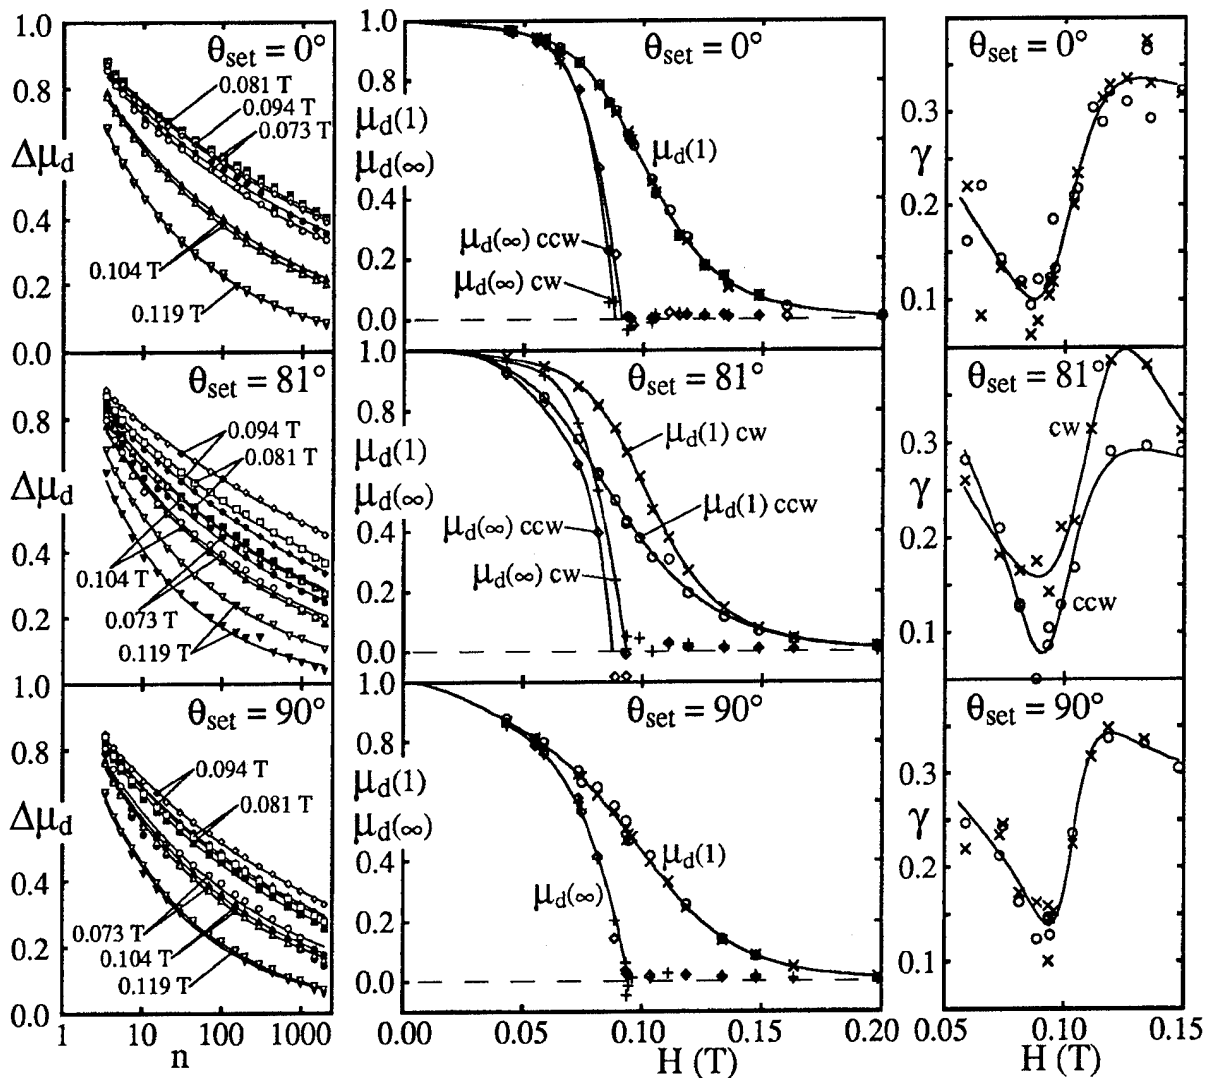

FIG. 1. Analysis of the angular dependence of the magnetization of a "FUJI FR metal" recording tape, first magnetized in the direction θ_{set} at $\mu_0 H_s = 1.2$ T and then measured in a field H_m . The dipolar component of the magnetization along H_m is extracted using Eqs. (1) and (2) and plotted in the three panels on the left as $\Delta\mu_d = n^{-\gamma}$, defined in Eq. (4). For H_m as noted, for up to 2000 cycles, the filled points are for cw and the open points are for ccw rotations. The dependence of the parameters $\mu_d(1)$ and $\mu_d(\infty)$ in Eq. (4) on H_m is shown in the three middle panels for cw and ccw directions. The values of the power γ in Eq. (4) used to fit the data on the left are shown in the panels on the right with cw data designated by x's and ccw data by o's.

the changes become small. The field dependence of $\mu_d(1) - \mu_d(\infty)$ can be extracted from the middle panels of Fig. 1 where we show $\mu_d(1)$ and $\mu_d(\infty)$.

The data in the middle panels of Fig. 1 are normalized to the magnitude of the remanence μ_r at $\theta_{\text{set}} = 0$, measured by rotation in zero field after saturation. The dependence of μ_r on θ_{set} has been reported and analyzed previously;⁷ $\mu_r(\theta_{\text{set}})$ is shown in the top panel of Fig. 2, also normalized to μ_r at $\theta_{\text{set}} = 0$. The values of γ used in each fitting are shown in the right-hand panels of Fig. 1. The curves in these panels are empirical fits to guide the eye.

There are no significant differences between the cw and ccw measurements for $\theta_{\text{set}} = 0$ or 90° . This is expected if the distribution of particle axes is symmetric with respect to the tape direction. There is a significant difference between cw and ccw rotations for $\theta_{\text{set}} \neq 0$ or 90° . This effect is largest for $\theta_{\text{set}} \sim 81^\circ$ which is a ccw rotation from the tape axis. When the dipole is written at 81° , ccw rotation drags the net mo-

ment toward 90° , enhancing the flipping, while cw rotation from drags it back toward 0° enhancing stability. Thus one anticipates bigger changes in the initial cycles for the ccw rotations. This is shown in the central panel of Fig. 1 where $\mu_d(1)$ is definitely smaller for ccw than for cw rotations.

Note that the curves in the mid panels of Fig. 1 bear some resemblance to the temperature dependence of the magnetization for a typical ferromagnetic material; the field dependence for $\mu_d(1)$ corresponds to the temperature dependence of the magnetization in a large applied field, while the field dependence for $\mu_d(\infty)$ corresponds to $M_s(T)$. The power laws observed here are related to a form of critical behavior, popularized recently as self-organized criticality, one example being the cascades occurring when adding grains of sand to a sand pile.¹

Note that the extrapolation to $n = \infty$ produces positive dipole moments for $H < H_{\text{crit}}$ and no moment for H sufficiently larger than H_{crit} . H_{crit} is just below the smallest of the

FIG. 2. The dependence on θ_{set} of the parameters in Eq. (4) for $\mu_0 H_m = 0.094$ T. In the top panel, the dependence on θ_{set} of $\mu_d(1)$ for cw and ccw rotations are compared with that for the remanent moment μ_r . The dependence on θ_{set} of γ for cw and ccw rotations are shown in the bottom panel. The angles $\beta_d(1)$ of the dipolar components $\mu_d(1)$ are shown as a function of θ_{set} in the middle panel by plotting the difference between the angles and θ_{set} for cw and ccw rotations. The angle between the remanent moments β_r and θ_{set} are plotted in the same way for comparison. The differences between $\beta_d(1)$ and $\beta_{\Delta d}$, defined in the text, are also shown in the middle panel. The solid lines in all cases are empirical fits to guide the eye and extract angles that measure the offsets of symmetry points from 90 for cw and ccw rotations.

coercive fields $H_c(\theta_{\text{set}})$ measured by reversing fields at each θ_{set} .⁶ Very close to H_{crit} the extrapolated moments go slightly negative. Most likely this is a comment on the difficulty of extrapolation of real data when γ is as low as 0.1, but it might also raise questions about the adequacy of the simple power law. (The data for $H_m \approx H_{\text{crit}}$ do not justify an expression with more than three parameters.) That the smallest values of γ occur for H_m close to H_{crit} can be taken as another indication of the critical nature of the phenomena. The behavior for $H_m \approx H_{\text{crit}}$ is shown in more detail in Fig. 2 where the dependence of the various parameters on θ_{set} is analyzed.

The dependence on θ_{set} of the parameters $\mu_d(1)$ for cw and ccw rotations is shown in the top panel of Fig. 2 for

$\mu_0 H_m = 0.094$ T. Recall that these are extrapolated quantities, not measured, but after normalization they bear a striking relation to the remanent moments, also shown here. The normalization is to the value for $\theta_{\text{set}} = 0$ at this field. The curves for cw and ccw are mirror images, offset from 90° by about 5°. The sections for cw for $\theta_{\text{set}} < 90^\circ$ and for ccw for $\theta_{\text{set}} > 90^\circ$ coincide with the curve for $\mu_r(\theta_{\text{set}})$ normalized to μ_r at $\theta_{\text{set}} = 0$.

The dependence of the power law exponent γ on both θ_{set} and the direction of rotation are shown in the bottom panel of Fig. 2 for $\mu_0 H_m = 0.094$ T. Though the data are rather scattered, due to the small values of γ and the limit of 2000 cycles, there is clear evidence for a variation of γ both with direction of rotation and with θ_{set} near 90°.

The angle of the moment, $\beta_d(n)$ in Eq. (3), is zero for $\theta_{\text{set}} = 0$ and close to 90° for $\theta_{\text{set}} = 90^\circ$. For intermediate θ_{set} , the angle of the moment deviates from θ_{set} with the maximum effect coming near $\theta_{\text{set}} = 60^\circ$ or 75° depending on direction of rotation. This is similar to the dependence of the angle β_r of the remanence on θ_{set} as previously discussed⁷ and shown as the heavy line in the central panel of Fig. 2, where we plot $\theta_{\text{set}} - \beta_r(\theta_{\text{set}})$. We introduce two parameters to describe the change of the angles of the moment with cycle number, $\beta_d(1)$ and $\beta_{\Delta d}$, which are found by fitting $\mu'_d(n)$ and $\mu''_d(n)$ with Eq. (4) to obtain $\mu'_d(1)$, $\mu''_d(1)$, $\mu'_d(\infty)$, and $\mu''_d(\infty)$. $\beta_d(1)$ is calculated using Eq. (3) with $\mu'_d(1)$ and $\mu''_d(1)$ and $\beta_{\Delta d}$ is calculated using Eq. (3) with $\mu'_d(\infty)$ and $\mu''_d(\infty)$. $\beta_{\Delta d}$ is found from the angle of the vector difference between the extrapolated moments at $n=1$ and $n=\infty$,

$\beta_{\Delta d} = \arctan\{[\mu''_d(1) - \mu''_d(\infty)]/[\mu'_d(1) - \mu'_d(\infty)]\}$. If the moments extrapolated to ∞ were zero, there should be no difference between $\beta_d(1)$ and $\beta_{\Delta d}$, but there seems to be a small systematic difference near 90° that correlates with whether the rotation is cw or ccw.

We have made detailed theoretical analyses of the response of noninteracting Stoner–Wohlfarth particles with uniaxial anisotropy for which there are distributions of axes and strengths of the anisotropy in order to separate the single-particle behavior from that of interacting particles. We have carried out computer simulations that show the presence of cascades of interacting particles in the reversal process. Also, we have developed a cleaner experimental approach in which we determine the remanent magnetic dipole at each angle in each cycle for each field. This done by rotating the sample in field H_m by a given angle then lowering the field from H_m to zero before measuring the remanence while rotating through 360°. These topics will be presented elsewhere.

We consider the quantum antiferromagnet with easy-plane exchange anisotropy, namely, the antiferromagnetic XXZ model, on the square lattice. Its classical counterpart, compared to the planar model shows a reduction of the critical temperature T_{BKT} of the Berezinskii–Kosterlitz–Thouless phase transition, that is a consequence of the thermal out-of-plane fluctuations. For the quantum system we use the pure-quantum self-consistent harmonic approximation to calculate how much the effective exchange interaction is weakened as an effect of the pure-quantum part of the fluctuations. One can then predict the further reduction of T_{BKT} with respect to the corresponding classical system. The theory works well in a wide range of values of the easy-plane anisotropy. In the extreme case of the spin- $\frac{1}{2}$ model, the result is compatible with the estimate of T_{BKT} obtained by previous quantum Monte Carlo simulations. When the anisotropy is weak the theory leads to an unphysical “isotropization” due to the use of the Villain spin-boson transformation. © 1996 American Institute of Physics. [S0021-8979(96)01208-9]

The two-dimensional antiferromagnetic XXZ model is described by the general Hamiltonian

$$\hat{\mathcal{H}} = \frac{1}{2} J \sum_{\mathbf{i}, \mathbf{d}} (\hat{S}_{\mathbf{i}}^x \hat{S}_{\mathbf{i}+\mathbf{d}}^x + \hat{S}_{\mathbf{i}}^y \hat{S}_{\mathbf{i}+\mathbf{d}}^y + \lambda \hat{S}_{\mathbf{i}}^z \hat{S}_{\mathbf{i}+\mathbf{d}}^z), \quad (1)$$

where the index $\mathbf{i} \equiv (i_1, i_2)$ runs over the sites of a two-dimensional lattice, and $\mathbf{d} \equiv (d_1, d_2)$ represents the displacements of the z nearest neighbors of each site.

The sum describes an exchange interaction $J > 0$ between nearest-neighbor spins, with an easy-plane anisotropy $\lambda \in [0, 1)$.

The lattice is such that it can be considered as two interpenetrating identical sublattices (the “positive” sublattice and the “negative” one), in such a way that the nearest neighbors of any site in a sublattice belong to the other one; in other words, we do not consider lattices with frustrated bonds.

For $\lambda = 0$ the above Hamiltonian describes the XX0 model, often (improperly) called “quantum XY model”; it is to be noticed that the XX0 model is equivalent to its ferromagnetic counterpart. Indeed, the canonical transformation

$$(\hat{S}_{\mathbf{i}}^x, \hat{S}_{\mathbf{i}}^y, \hat{S}_{\mathbf{i}}^z) \rightarrow [(-)^i \hat{S}_{\mathbf{i}}^x, (-)^i \hat{S}_{\mathbf{i}}^y, \hat{S}_{\mathbf{i}}^z],$$

where $(-)^i = \pm 1$ is the sign of the sublattice containing the site \mathbf{i} , transforms the antiferromagnetic XX0 model into the ferromagnetic XX0 model. More generally, for the XXZ model this canonical transformation is equivalent to put $J \rightarrow -J$ and $\lambda \rightarrow -\lambda$.

The classical counterpart of the Hamiltonian (1) is obtained by associating to each spin operator $\hat{S}_{\mathbf{i}}$ a classical vector $\mathbf{S}_{\mathbf{i}}$ of given length \tilde{S} . In terms of unit vectors $\mathbf{s}_{\mathbf{i}} = \mathbf{S}_{\mathbf{i}}/\tilde{S}$,

$$\mathcal{H} = \frac{1}{2} \epsilon \sum_{\mathbf{i}, \mathbf{d}} (s_{\mathbf{i}}^x s_{\mathbf{i}+\mathbf{d}}^x + s_{\mathbf{i}}^y s_{\mathbf{i}+\mathbf{d}}^y + \lambda s_{\mathbf{i}}^z s_{\mathbf{i}+\mathbf{d}}^z), \quad (2)$$

with the exchange energy $\epsilon = J\tilde{S}^2$; in the following we will only use the dimensionless temperature $t = T/\epsilon$. The choice of \tilde{S} is ambiguous, since values as \tilde{S} or $\sqrt{\tilde{S}(\tilde{S}+1)}$ are both reasonable: a different answer, $\tilde{S} = S + \frac{1}{2}$, is suggested by the pure-quantum self-consistent harmonic approximation (PQSCHA) to the quantum Hamiltonian (1), as we will show below. The minimum-energy configuration of the classical Hamiltonian corresponds to the Néel state: the two sublattices are ordered ferromagnetically in the xy plane, but in opposite directions.

In contrast to the quantum case, in the classical case the ferromagnetic and the antiferromagnetic cases are fully equivalent (i.e., $J \rightarrow -J$), as far as the static properties are concerned.

In the approximation of dominating easy-plane anisotropy the z components of the spins are neglected and the so-called *planar* model (frequently “classical XY model”) is obtained. Since the spins are reduced to two-component vectors in the xy plane, $\mathbf{s}_{\mathbf{i}} = (\cos \varphi_{\mathbf{i}}, \sin \varphi_{\mathbf{i}})$, its Hamiltonian can be written in terms of the azimuthal angles, $\mathcal{H} = \frac{1}{2} \epsilon \sum_{\mathbf{i}, \mathbf{d}} \cos(\varphi_{\mathbf{i}} - \varphi_{\mathbf{i}+\mathbf{d}})$. This is the prototype system that undergoes the Berezinskii–Kosterlitz–Thouless (BKT) phase transition^{1–3} occurring at the temperature $t_{\text{BKT}} = T_{\text{BKT}}/\epsilon \approx 0.89$, that has been calculated by Monte Carlo simulations.^{4,5} The antiferromagnetic order parameter $\langle (-)^i \mathbf{s}_{\mathbf{i}} \rangle$, vanishes at any nonzero temperature, and the mechanism underlying the transition is the unbinding of vortex pairs.^{2,6} For $t < t_{\text{BKT}}$ the correlation function $\langle (-)^i \mathbf{s}_{\mathbf{i}} \cdot \mathbf{s}_{\mathbf{j}} \rangle = \langle \cos(\varphi_{\mathbf{i}} - \varphi_{\mathbf{j}}) \rangle$ displays a power law decay, $\sim |\mathbf{i} - \mathbf{j}|^{-\eta(t)}$, whereas for $t > t_{\text{BKT}}$ the behavior is exponen-

tial; moreover, the susceptibility has an exponential divergence for $t \rightarrow t_{\text{BKT}}^+$.

With the inclusion of the out-of-plane components s_i^z of the spins still a BKT transition is expected at a finite temperature $T_{\text{BKT}}(\lambda)$, which vanishes logarithmically^{7,8} in the isotropic limit $\lambda \rightarrow 1$. Monte Carlo simulations for the classical XXZ model that provide useful data have been published in Ref. 9.

The quantum system (1) preserves the rotational symmetry around the z axis; therefore, from universality arguments, it displays the qualitative features of a BKT system as its classical analogue, with quantitative modifications of the critical parameters arising from quantum fluctuations.

Due to the absence of demagnetizing fields, an experimental observation of BKT behavior should be easier in antiferromagnetic XXZ systems (a $S=5/2$ compound with magnetic Mn ions is under study¹⁰). The aim of this work is to apply a recent theoretical approach, the PQSCHA,¹¹ to the quantum antiferromagnetic XXZ model (1). The ferromagnetic system has been already treated by PQSCHA.¹² In Ref. 13 one also finds—for the ferromagnetic case—an outline of the derivation of the effective Hamiltonian \mathcal{H}_{eff} in terms of classical spins, a procedure that involves the Villain transformation from quantum spin to bosonic variables,¹⁴ and the identification of the classical counterpart of the transformed Hamiltonian by the prescription of Weyl ordering.¹⁵ It is just the Weyl ordered form of the Villain transformed spin operators that leads to the identification $\tilde{S} = S + \frac{1}{2}$.¹⁶

Eventually, the PQSCHA recipe gives the following effective Hamiltonian for the antiferromagnetic XXZ model:¹⁷

$$\mathcal{H}_{\text{eff}} = \frac{\epsilon}{2} j_{\text{eff}} \sum_{i,d} (s_i^x s_{i+d}^x + s_i^y s_{i+d}^y + \lambda_{\text{eff}} s_i^z s_{i+d}^z) + N \epsilon G(t). \quad (3)$$

As in Eq. (2), $\{s_i\}$ are classical normalized spin variables. Within the PQSCHA,¹¹ the contribution of quantum fluctuations (treated up to the harmonic level) is embodied in the following dimensionless interaction parameters:

$$j_{\text{eff}}(S, \lambda, t) = (1 - \frac{1}{2} D_{\perp})^2 e^{-1/2 \mathcal{D}_{\parallel}}, \quad (4)$$

$$\lambda_{\text{eff}}(S, \lambda, t) = \lambda (1 - \frac{1}{2} D_{\perp})^{-1} e^{1/2 \mathcal{D}_{\parallel}}, \quad (5)$$

while $G(t)$ is an additive renormalization quantity that does not enter the calculation of operator averages. The self-consistent renormalization parameters

$$D_{\perp} = \frac{1}{2\tilde{S}} \frac{1}{N} \sum_{\mathbf{k}} \frac{b_{\mathbf{k}}}{a_{\mathbf{k}}} (\coth f_{\mathbf{k}} - f_{\mathbf{k}}^{-1}), \quad (6)$$

$$\mathcal{D}_{\parallel} = \frac{1}{2\tilde{S}} \frac{1}{N} \sum_{\mathbf{k}} (1 - \gamma_{\mathbf{k}}) \frac{a_{\mathbf{k}}}{b_{\mathbf{k}}} (\coth f_{\mathbf{k}} - f_{\mathbf{k}}^{-1}) \quad (7)$$

represent, within the PQSCHA, the pure-quantum part of the square fluctuations^{11,16} of the z -components of the spins and of the relative azimuthal angle of nearest-neighbor spins, respectively, and are decreasing functions of t and S , vanishing both for $t \rightarrow \infty$ or $S \rightarrow \infty$. They depend on t , S , and λ through the quantities

$$a_{\mathbf{k}}^2 = z e^{-1/2 \mathcal{D}_{\parallel}} (1 + \lambda_{\text{eff}} \gamma_{\mathbf{k}}), \quad (8)$$

FIG. 1. The effective exchange coupling $j_{\text{eff}}(S, \lambda=0.5, t)$ for the XX0 antiferromagnetic model vs temperature $t = T/\epsilon$ and for different values of the spin S (solid lines). The energy scale is $\epsilon = JS^2 = J(S + \frac{1}{2})^2$. The dotted lines are the curves $t/t_{\text{BKT}}^{(c)}(\lambda)$ for $\lambda=0.5$ and 0.95 . See the text for the discussion about the use of such curves for graphically solving Eq. (10).

$$b_{\mathbf{k}}^2 = z (1 - \frac{1}{2} D_{\perp})^2 e^{-1/2 \mathcal{D}_{\parallel}} (1 - \gamma_{\mathbf{k}}), \quad (9)$$

$f_{\mathbf{k}} = a_{\mathbf{k}} b_{\mathbf{k}} / (2\tilde{S} t)$, $\gamma_{\mathbf{k}} = z^{-1} \sum_{\mathbf{d}} \cos(\mathbf{k} \cdot \mathbf{d})$, and \mathbf{k} is a wave vector varying in the first Brillouin zone. Therefore, the exchange energy is renormalized by the factor j_{eff} , and the easy-plane anisotropy is weakened ($\lambda_{\text{eff}} \geq \lambda$), due to the cooperative effect of in-plane and out-of-plane pure-quantum fluctuations. Their typical temperature behavior in the case of the square lattice is reported in Figs. 1, and 2, respectively. For $S \rightarrow \infty$, i.e., in the classical limit, $j_{\text{eff}} \rightarrow 1$ and $\lambda_{\text{eff}} \rightarrow \lambda$. We notice that the integrals of the pure-quantum fluctuation parameters, Eqs. (6) and (7), get the main contribution from the high-frequency part of the effective magnon spectrum $\omega_{\mathbf{k}} = (JS/\hbar) a_{\mathbf{k}} b_{\mathbf{k}}$, just because the pure-quantum part of the square fluctuations is obtained by subtracting from the full (harmonically approximated) expression the corresponding classical part (i.e., the leading behavior for $f_{\mathbf{k}} \rightarrow 0$); on the other hand, those effects due to the presence of nonlinear excitations (vortices) would mainly affect the low-frequency part; i.e., they are essentially “classical” and therefore they cannot sensitively change D_{\perp} and \mathcal{D}_{\parallel} .

Using the PQSCHA formalism¹¹ one can calculate averages and correlations by means of classical expressions in-

FIG. 2. The effective anisotropy parameter λ_{eff} for the XX0 antiferromagnetic model vs temperature and for spin $S=1$ and $S=5/2$, at different values of λ . For high values of λ the curves reach the isotropic value $\lambda_{\text{eff}}=1$.

FIG. 3. The critical temperature t_{BKT} of the XXZ antiferromagnetic model vs the value of the anisotropy λ and for different values of the spin S . The classical values (squares) from Ref. 9 are 0.695 ± 0.005 , 0.683 ± 0.005 , 0.59 ± 0.01 , 0.55 ± 0.01 , for $\lambda=0, 0.5, 0.9$, and 0.95 , respectively. The circles report QMC results from Refs. 21 and 22. Note that $t_{\text{BKT}}(S, \lambda)$ decreases when λ is increased, and the theory would lead to the disappearance of the transition by a mechanism of “isotropization.”

volving the Boltzmann factor corresponding to the effective Hamiltonian. In the present case the classical average with the effective Hamiltonian is defined as

$$\langle \dots \rangle_{\text{eff}} = \mathcal{Z}^{-1} \left(\prod_i \int d\mathbf{s}_i \right) (\dots) e^{-\beta \mathcal{H}_{\text{eff}}}.$$

In order to obtain the PQSCHA thermal average of a quantum observable, the dots are to be replaced by a phase-space function that is obtained by Gaussian smearing, on the scale of the pure-quantum fluctuations, of the Weyl symbol associated with the same observable.^{11,16} In this way we find expressions for the in-plane correlations

$$\langle \hat{S}_i^x \hat{S}_j^x \rangle = \tilde{S}^2 (1 - \frac{1}{2} D_{\perp}^2) e^{-1/2 \mathcal{L}_{\parallel}} e^{D_{\parallel}^2 \langle \hat{S}_i^x \hat{S}_j^x \rangle_{\text{eff}}},$$

where the renormalization parameters D_{ij}^{\parallel} (Ref. 17) for the relative azimuthal fluctuations between sites \mathbf{i} and \mathbf{j} are such that $D_{ij}^{\parallel} \rightarrow 0$ for $|\mathbf{i} - \mathbf{j}| \rightarrow \infty$. Therefore, the asymptotic behavior and the correlation length are just those obtained for the effective classical model. The quantum transition temperature $t_{\text{BKT}}(S, \lambda)$ can then be estimated from the knowledge of the corresponding classical one $t_{\text{BKT}}^{(\text{cl})}(\lambda)$, with a self-consistency arising from the dependence on t and λ of the renormalized interaction parameters, Eqs. (4) and (5):

$$\frac{t_{\text{BKT}}(S, \lambda)}{j_{\text{eff}}(S, \lambda, t_{\text{BKT}})} = t_{\text{BKT}}^{(\text{cl})}[\lambda_{\text{eff}}(S, \lambda, t_{\text{BKT}})]. \quad (10)$$

It is rather easy to solve this equation for the XX0 model,¹² since $\lambda_{\text{eff}}=0$ for $\lambda=0$. In order to solve it for $\lambda \neq 0$ we have made a rough fit of $t_{\text{BKT}}^{(\text{cl})}(\lambda)$ using the available values⁹ reported as squares in Fig. 3. The fit, as shown in the figure, is considered only for $\lambda < 0.8$, in such a way that we do not run into the zone where $t_{\text{BKT}}^{(\text{cl})} \sim [-\ln(1-\lambda)]^{-1}$ vanishes logarithmically.⁷ Then Eq. (10), rewritten as $j_{\text{eff}} = t_{\text{BKT}}/t_{\text{BKT}}^{(\text{cl})}$,

can be solved graphically in Fig. 1 in a recursive way: one estimates the transition temperature using $t_{\text{BKT}}^{(\text{cl})}(\lambda)$ and then the value of λ_{eff} at this temperature is taken for redoing the procedure, and so on. The results obtained in this way are also reported for different values of S in Fig. 3.

For the XX0 model there is a possible comparison with other data in the extreme case of $S = \frac{1}{2}$. Our result is $t_{\text{BKT}} = 0.36$ and compares very well with the values found by high-temperature expansions¹⁸ (0.39), by real-space renormalization group techniques¹⁹ (0.40), and by recent quantum Monte Carlo (QMC) simulations^{20,21} (0.353 ± 0.003). For $\lambda = 0.5$, we have $t_{\text{BKT}} = 0.30$, to be compared with the QMC value²² 0.325 ± 0.007 .

When λ is large enough, we see from Fig. 2 that it may happen that $\lambda_{\text{eff}}(S, \lambda, t) \geq 1$. When $\lambda_{\text{eff}} = 1$ is reached the effective Hamiltonian becomes isotropic, and the theory therefore predicts the disappearance of the BKT transition at sufficiently high values of $\lambda \geq \lambda_c(S)$ (some values are $\lambda_c = 0.58, 0.75, 0.85, 0.90, 0.92$, for $S = \frac{1}{2}, 1, \frac{3}{2}, 2, \frac{5}{2}$, respectively). However, this situation has to be considered with care, because the derivation of the effective Hamiltonian relies on the validity of the Villain transformation,¹⁴ which is meaningful only for easy-plane systems. Indeed, for high λ the out-of-plane fluctuations become so strong that the assumed dominant easy-plane character becomes meaningless. The breakdown does not occur for $\lambda \ll \lambda_c$, of course, and therefore does not affect the results reported in Fig. 3.

The suppression of the BKT transition by “effective isotropization” is therefore unlikely to be physical, as confirmed also by quantum Monte Carlo simulations of the $S = \frac{1}{2}$ XXZ antiferromagnet.²² At $\lambda = 0.90$ and 0.98 the BKT behavior is still observed, with substantially high transition temperatures, $t_{\text{BKT}} = 0.285$ and 0.25 , respectively.

Homogeneous magnetization dynamics below T_c of EuO: Effects of spin waves and anisotropy

A. Flosdorff, D. Görnitz, and J. Kötzler

Institut für Angewandte Physik, Universität Hamburg, Jungiusstr. 11, D-20355 Hamburg, Germany

Using a broadband reflectometer, the dynamic susceptibility $\chi(\omega)$ of a EuO sphere has been measured from 0.3 to 20 GHz at temperatures ranging between 4.2 K and $T_c=69.5$ K. For fields applied parallel to the hard [100] direction one heavily damped Lorentzian is observed which for internal fields H larger and smaller than the anisotropy field arises from the dynamics of the homogeneous and the wall magnetization, respectively. For fields near H_A applied along one of the easy [111] axes, both processes contribute to $\chi(\omega)$ but with increased and decreased values of the resonances and damping frequencies of the homogeneous and wall processes, respectively. The homogeneous process is identified by the static susceptibility $\chi_z(0)$ which obeys the $H^{-1/2}$ divergence due to spin waves. Its line shape is explained by a frequency variation of the kinetic coefficient of the relaxation damping, $L_z(\omega)=L_z(0)/[1+(i\omega/\omega_c)]$. The characteristic frequency, $\omega_c/2\pi=18$ GHz, turns out to be independent of temperature and magnetic field, and is related to the relaxation rate of the long-wavelength longitudinal magnetization fluctuations. The field and temperature variation of the kinetic coefficient of the relaxation can be described by the same scaling function, $L_z(\chi_z(T,H))$, as previously observed above T_c . Based on results of numerical mode-coupling work, this behavior is associated with the dipolar anisotropy of the magnetic fluctuations. © 1996 American Institute of Physics. [S0021-8979(96)04208-4]

Extensive investigations of the homogeneous magnetization dynamics on the cubic chalcogenides EuS and EuO¹⁻⁴ revealed an almost perfect agreement with predictions of mode-coupling work for dipolar Heisenberg ferromagnets valid for the unmagnetized state above T_c .⁵ The kinetic coefficient L_z of the magnetic relaxation rate, $\Gamma_z=L_z/\chi_z$, displayed a crossover from a critical speeding-up, $L_z\sim\chi_z^{7/4}$, arising from isotropic exchange dominated fluctuations ($\chi_z<1$), to $L_z=\text{const}$ for $\chi_z>1$, where the dipolar anisotropy becomes effective. This dynamic crossover is described by a universal scaling function, $L_z(\chi_z)$, which for $H=0$ has been verified for numerous Heisenberg-like ferromagnets above T_c , including EuO.¹ More recently it was found for EuS that the same scaling function could also explain the variation of L_z with field² and with temperature below T_c ,^{3,4} i.e., $L_z(T,H)=L_z(\chi_z(T,H))$.

Here we communicate first results of a corresponding investigation below the Curie temperature of EuO, $T_c=69.5$ K. The work is intended to explore possible effects on the dynamics of the homogeneous magnetization by the stronger exchange and by the cubic magnetic anisotropy, where the latter is one order of magnitude larger in EuO than in EuS.⁶ It is also the hope that the results reported here will motivate further theoretical activity towards a more detailed understanding of the dynamics in the ordered regime of real ferromagnets, similar to that gained above T_c .

By means of a broadband microwave reflectometer described elsewhere,^{4,7} we measured the linear complex susceptibility $\chi(\omega)$ parallel to the applied field H_z at fixed temperatures. In order to examine the effect of the cubic anisotropy, the field was aligned parallel to one easy [111] and also to one hard [100] direction of a single crystalline sphere ($\varnothing=3$ mm). For example, Fig. 1 shows the frequency variation of $\chi(\omega)$ recorded at $T=0.43 T_c$. There the anisotropy field attains the value $H_A=110$ Oe,⁶ which has been

bracketed by the two chosen internal fields, $H=H_z-N_zM$. The magnetizations required for the demagnetization correction have been determined on the same sphere by a superconducting quantum interference device (SQUID) magnetometer (see inset to Fig. 2).⁸ Not unexpectedly, the dynamic susceptibility becomes independent of orientation for $H=700$ Oe $\gg H_A$, whereas a pronounced anisotropy emerges for $H=50$ Oe $<H_A$.

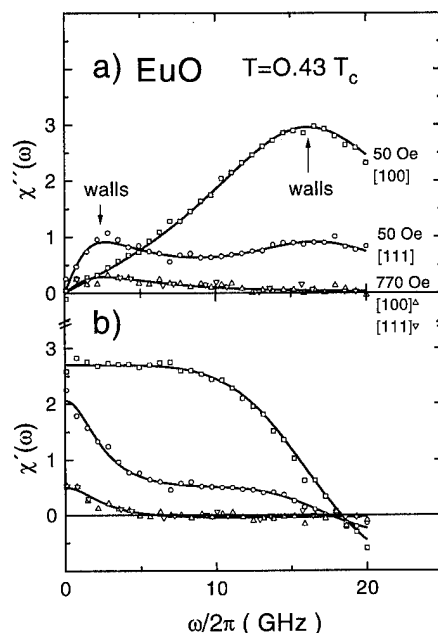

FIG. 1. Absorption (a) and dispersion (b) of the dynamic susceptibility measured parallel to the applied field on a EuO sphere in fields smaller and larger than the anisotropy field $H_A(0.43T_c)\approx 110$ Oe along two sample orientations. Full lines represent fits to single and double damped harmonic oscillator, Eqs. (1) and (2).

FIG. 2. Fitted internal static susceptibility normalized to relative temperature T/T_c vs scaled internal magnetic field for two sample orientations at temperatures $T \geq 0.43T_c$ for internal fields $H > H_A$ [100], [111] and at $T = 0.43T_c$ for fields $H_A < H$ [111]. Inset: magnetization data along [100] and [111] showing anisotropy below internal fields $H \leq H_A$.

Like the corresponding results on EuS,^{3,4} the data can be well fitted either by one or by a sum of two heavily damped Lorentzians (solid lines in Fig. 1)

$$\chi(\omega) = ([\chi_z(\omega) + \chi_w(\omega)]^{-1} + N_z)^{-1}, \quad (1)$$

where the “internal” dynamic susceptibilities are given by

$$\chi_\alpha^{-1}(\omega) = \chi_\alpha^{-1} + \frac{i\omega}{L_\alpha} - \frac{\omega^2}{\Omega_\alpha^2}, \quad \alpha = z, w. \quad (2)$$

Again, the situation is simpler for $H \gg H_A$. Here only one process is effective, which obviously has to be associated with the dynamics of the homogeneous magnetization, $\chi_z(\omega)$. For $\mathbf{H} \parallel [111]$ and $H \leq H_A$, on the other hand, two processes occur around 3 and 17 GHz. If the same internal field is applied parallel to the hard [100] direction, again there is only one Lorentzian at high frequencies. This high-frequency dispersion as well as the low-frequency one for $\mathbf{H} \parallel [111]$ have been traced down to $H_z = 0$ and were identified with domain wall motion.⁹

The designation of the other process as the homogeneous dynamics can be further substantiated by the field and temperature variation of the static susceptibility χ_z . In Fig. 2 the values fitted from data for $T \geq 0.43T_c$ and scaled by the reduced temperature T/T_c are plotted versus the internal field multiplied by $m_z^3(T, H) = (M(T, H)/M_0)^3$, where $M_0 = 24.8$ kOe is the saturation magnetization. This representation allows for a direct comparison to a prediction based on spin-wave fluctuations,¹⁰ which in this form was successfully tested for EuS.¹¹ The data, except those for the lowest fields, display the characteristic divergence, $\chi_z = A_0(T/T_c)(Hm_z^3)^{-1/2}$, with $A_0 = 0.15(5) \text{ kOe}^{1/2}$. In the dipolar anisotropic regime, $\chi_z > 1$, this amplitude is given by $A_0 = (k_B T_c / 16\pi\mu_0 M_0^{3/2}) q_d^{3/2}$,¹⁰ which implies for the so-called dipolar wave number $q_d = 0.19(3) \text{ \AA}^{-1}$. This value is in reasonable accord with $q_d = 0.15 \text{ \AA}^{-1}$ (see Ref. 12) inferred from the $H = 0$ paramagnetic susceptibility and correlation length of EuO. It is interesting to note that—similar as in the case of EuS¹¹—even susceptibilities at rather high temperatures, $T = 0.99T_c$, obey the $H^{-1/2}$ divergence. This indicates

FIG. 3. Scaling behavior of the kinetic coefficient L_z and the resonance frequency Ω_z in terms of the internal susceptibility along two crystal orientations for $T \geq 0.43T_c$ and $H > H_A(T)$. Full lines correspond to solutions of the mode-coupling equations strictly valid above T_c and for $H = 0$. Inset: L_z and Ω_z for fixed temperature $T = 0.43T_c$ at internal fields $H < H_A$.

that the spin-wave induced singularity is rather robust against longitudinal critical fluctuations. Even more surprising is the fact that $\chi_z(T = 0.43T_c, H < H_A)$ for $\mathbf{H} \parallel [111]$ also obeys the $H^{-1/2}$ -scaling (open triangles in Fig. 2). Hence this singularity of χ_z also seems to be unaffected by the cubic anisotropy if the field is applied along the easy direction.

We now discuss the behavior of the kinetic coefficient of the damping, $L_z(T, H)$, and the intrinsic resonance frequency, $\Omega_z(T, H)$, of the homogeneous process, obtained from the fits to Eqs. (1) and (2). Based on the validity of the scaling behavior detected for L_z in the magnetized state of EuS,³⁻⁵ we depict our results for $L_z(T, H)$ and $\Omega_z(T, H)$ in Fig. 3 versus the static susceptibility, $\chi_z(T, H)$. Indeed we find that for $H > H_A$ and $T \geq 0.43T_c$ each of both quantities collapses on a single curve. This means that the temperature and field variations are determined entirely by the static susceptibility. The inset to Fig. 3 illustrates for $T = 0.43T_c$ that this scaling property of Ω_z and L_z , however, is violated for internal fields smaller than the anisotropy field H_A if \mathbf{H} is parallel to [111]. Since, in this case, Ω_z and L_z are significantly enhanced over the L_z scaling function obtained for $H > H_A$, while the static susceptibility follows the spin-wave law, $\chi_z \sim H^{-1/2}$, the dynamics appear to be more sensitive against the anisotropy than the static properties.

Theoretical considerations of the dynamics in the magnetized state of dipolar Heisenberg ferromagnets, which include fluctuations, exist only for $\mathbf{q} > 0$ (see Ref. 13) so that our discussion rests only on purely phenomenological arguments. First of all, we emphasize that, according to Fig. 3 the experimental kinetic coefficients agree almost perfectly with the scaling function, $L_z^{MC}(\chi_z(T, H)) = L_z^{MC}(\infty)[1 + \chi_z^{-1}(T, H)]^{-7/4}$ predicted by the mode coupling (MC) work⁵ for $T \geq T_c$ and $H = 0$ (solid curve in Fig. 2). This implies that below T_c , at least above the dipolar crossover, i.e., for $\chi_z \geq 1$, the effect of the dipolar anisotropy, which also determines the nonsingular value of L_z at T_c , $L_z(\infty) = (g\mu_B/\hbar^2)\sqrt{k_B T_c q_d^{5/2}}$,^{1,5} diminishes in the same manner as above T_c . The question of whether below T_c the dipolar

anisotropy governs the dynamics of the $q \rightarrow 0$ fluctuations in a similar manner as above T_c (see Ref. 14) is currently investigated by inelastic neutron scattering.¹⁵

The Lorentzian shape of $\chi_z(\omega)$ and the scaling behavior of the resonance frequency Ω_z can be explained by a pure relaxational dynamics, $\chi_z(\omega) = [\chi_z^{-1} + i\omega/\hat{L}_z(\omega)]^{-1}$, containing a frequency-dependent kinetic coefficient, $\hat{L}_z(\omega) = L_z/(1 + i\omega/\omega_c)$. This implies $\Omega_z = \sqrt{\omega_c L_z}$ (see Ref. 3) and in fact, assuming a constant value, $\omega_c/2\pi = 18(2)$ GHz, the scaling behavior of $\Omega_z(T, H)$ is well described by that of $L_z(T, H)$ [see Fig. 3]. This value for ω_c is rather close to the relaxation rate of the $q \rightarrow 0$ longitudinal fluctuations,² $\Gamma_\ell/2\pi = Aq_d^{5/2}/2\pi = 18(3)$ GHz calculated from the measured value for $A = \Gamma_\ell(q)/q^{5/2}$ (Ref. 16) and $q_d = 0.15(2) \text{ \AA}^{-1}$.¹² Such correspondence has been predicted by extending the MC approach⁵ for the damping of the homogeneous magnetization to finite frequencies.^{3,4} Because Γ_ℓ is much larger than the maximum frequency associated with the anisotropy, $\Gamma_A/2\pi = \gamma H_A(0) = 0.67$ GHz, it is plausible that the latter has no influence on $L_z(T, H)$.

There are, however, clear effects of the anisotropy if the internal field is reduced toward H_A . For $\mathbf{H} \parallel [100]$, where all easy directions enclose the same angle with \mathbf{H} , only one dynamic process appears (see Fig. 1). From the static susceptibility $\chi(0)$ we infer that this process arises from the homogeneous magnetization for internal fields larger than the anisotropy field and from the wall motion⁹ for $H < H_A$. In contrast, if \mathbf{H} is aligned parallel to one of the easy $[111]$ axes, we observe two processes for fields near H_A which arise

from both the homogeneous and the wall process. It emerges as main feature that in the transition region around H_A the kinetic coefficient and resonance of the homogeneous dynamics are enhanced while those of the wall motion are reduced.⁹ This signalizes a novel dynamical interference between both processes for the asymmetric configuration, which will be the subject of more detailed future work.¹⁷

The dilute insulating ferromagnet $\text{Fe}_{1-x}\text{As}_x[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$ is examined in single crystal form for several compositions spanning the range $x=0.014$ to $x=0.040$. For $x=0.014_3$ and $x=0.016_2$ crystals, the inverse molar susceptibility along the [101] ferromagnetic easy axis is quite linear in temperature for T greater than a few times T_c . In the case of $x=0.031_3$ and $x=0.040_2$ crystals, in contrast, significant curvature appears in χ^{-1} vs T throughout the 20–80 K temperature range. The initial (low-field) susceptibility along [101] for each crystal is measured in the critical region and analyzed via a standard power law form $\chi_0 = \Gamma t^{-\gamma}$, where $t = (T - T_c)/T_c$. T_c decreases with increasing x , but somewhat slowly. The critical exponent γ increases with increasing x , from 1.19 ± 0.01 near $x=0.014$ to 1.22 ± 0.01 near $x=0.040$. The prefactor Γ is significantly smaller for the two higher As crystals, probably due to increased disorder. The variation in γ is not entirely unexpected, since the pure material, which is a candidate Z_2xS_1 system, has an unusual set of critical exponents, including a large positive α . Thus new critical behavior on dilution can occur by the Harris criterion. © 1996 American Institute of Physics. [S0021-8979(96)01308-5]

I. INTRODUCTION

Previous examination^{1–4} of the novel pentacoordinate Fe^{3+} compound $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$ with $S=3/2$, Fig. 1, revealed unusual critical behavior at the 2.457 K ferromagnetic transition. Independent values of the exponents for the initial susceptibility, $\gamma=1.165 \pm 0.03$, and for the sublattice magnetization (from NMR data), $\beta=0.245 \pm 0.02$, were determined. Scaling analysis of magnetization isotherms yielded an independent pair of exponents $\beta=0.24 \pm 0.01$ and $\delta=5.65 \pm 0.15$, the latter exponent controlling behavior at the critical isotherm. The values of γ , β , and δ are consistent with the scaling relation $(\delta-1)\beta=\gamma$ within the experimental uncertainties. Only some sparse heat capacity data are available,⁵ but from these the provisional estimate $\alpha=0.38 \pm 0.06$ was inferred,³ a large value but consistent with the above in light of the scaling relation $\alpha=2-2\beta-\gamma$.

The above exponents differ substantially from theoretical values for any conventional universality class, e.g., 3D-Ising, to which structural considerations and the strongly anisotropic magnetic susceptibility and magnetization point. Ising model behavior can be rationalized based on the 4A_2 crystal field ground term and its large zero-field splitting.¹ Kawamura has studied the critical behavior of magnets where the ground state has Z_2xS_1 symmetry, i.e., an Ising-like chiral symmetry combined with an XY-like rotational symmetry.⁶ The latest values of the critical exponents for the 3D version of the Z_2xS_1 model are $\alpha=0.34 \pm 0.06$, $\beta=0.253 \pm 0.01$, $\gamma=1.13 \pm 0.05$ and, for the correlation length, $\nu=0.54 \pm 0.02$.⁷ From the scaling relation given earlier one also obtains $\delta=5.47 \pm 0.35$. These values agree remarkably well with those determined for $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$. Moreover, Z_2xS_1 symmetry may characterize a canted ferromagnet with Ising anisotropy, as our system is thought to be. Neutron investigations are underway on deuterated material.⁸

If $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$ is indeed an example of the Z_2xS_1 universality class study of the variation, if any, of its critical behavior with dilution is important. No theoretical predictions for the dilute Z_2xS_1 model are available, but from the Harris criterion⁹ the positive α value means that a change in critical behavior with dilution (disorder) is expected. In an earlier report¹⁰ an extremely dilute single crystal with $x=0.0039$ was examined. Relative to the pure system T_c was lower by only 0.011 K. A slight decrease in γ of ~ 0.015 was also observed, though this shift was not very much beyond experimental uncertainty. In the present work several crystals somewhat more concentrated in diamagnetic diluent are examined.

II. EXPERIMENT

Diamagnetic $\text{As}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$ was prepared as reported previously,¹⁰ as was $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$.¹ The substances were dissolved in methylene chloride to form solutions of nominal molar composition 10%/90%, 20%/80%, 30%/70%, and 40%/60% arsenic/iron complexes. Single crystals obtained on evaporating the solutions to dryness displayed a trend towards smaller size, and somewhat less regular shape, with increasing arsenic concentration. Crystals of

FIG. 1. (a) Molecular structure of $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$, (b) relation of molecular principal axes to principal axes of crystal susceptibility.

FIG. 2. Inverse molar susceptibility vs temperature along the [101] ferromagnetic easy axis for different composition single crystals of $\text{Fe}_{1-x}\text{As}_x[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$. For clarity the data are shifted up 4, 8, and 12 mol/emu for $x=0.016_2$, 0.031_3 , and 0.040_2 , respectively.

adequate size for magnetic measurements and of similar morphology to those of the pure iron compound were selected from each nominal composition batch. They were cleaved to expose the $(\bar{1}01)$ cleavage plane within which lie the monoclinic b axis and the [101] ferromagnetic easy axis. The masses of the crystals used in the measurements were 2.89, 3.16, 0.4561, and 0.6518 mg (the latter two weighed with a microbalance) for the 10%, 20%, 30%, and 40% As preparations, respectively. Chemical elemental analysis by atomic absorption spectrometry gave the following actual molar compositions: $x_{\text{As}}=0.016_2$, 0.014_3 , 0.031_3 , and 0.040_2 for the nominal 10%, 20%, 30%, and 40% crystal, respectively. Absolute uncertainties in mole fractions are estimated to be $\pm 5\%$ for the first two values and $\pm 10\%$ for the latter two. As previously,¹⁰ only a small fraction of the As complex in solution goes into the Fe-complex crystal lattice, probably because of molecular size considerations.

The magnetization of each single crystal was measured along the [101] axis using a Quantum Design MPMS7 SQUID magnetometer. The applied field was 15.0, 75.0, and 975.0 G for the 2–10, 10–20, and 20–80 K temperature ranges, respectively. The accuracy of the set field was checked by measuring M vs H between 50 and -50 G at 5 K for each crystal, observing linearity, and confirming that $M=0$ at $H=0$ to within ~ 0.5 G uncertainty. Susceptibilities, calculated as M/H , have been corrected for diamagnetism (-0.000212 emu/mol) and demagnetization. For each crystal the demagnetization factor N_{eff} , in $H(\text{internal})=H(\text{applied})-N_{\text{eff}}M_v$, where M_v is the volume magnetization, was calculated as the reciprocal of the levelled volume susceptibility below T_c . Only an effective demagnetization factor is obtained because the crystals, of hexagonal prismatic shape, cannot be worked into ellipsoids of revolution. The N_{eff} are 5.68, 4.00, 5.60, and 6.71 for the 10%, 20%, 30%, and 40% As-complex crystals, respectively. Temperatures were measured with a calibrated Ge-resistance thermometer below 38 K and a calibrated Pt-resistance thermometer above 38 K; absolute accuracies are $\pm 0.5\%$.

FIG. 3. Critical law fits to initial susceptibility along [101] for $x=0.014_3$ and 0.016_2 single crystals of $\text{Fe}_{1-x}\text{As}_x[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$. For clarity the $x=0.016_2 \log \chi_0$ are shifted up 0.2. T_c is in K and Γ in emu/mol.

III. MEASUREMENTS AND ANALYSIS

In Fig. 2 appear the inverse molar susceptibilities for each of the crystals. For $x=0.014_3$ and 0.016_2 , χ^{-1} is quite linear above 20 K, and deviations from linearity do not become marked until well below 10 K. Such behavior had also been seen for the pure material. For the $x=0.031_3$ and 0.040_2 samples, however, and more strongly for the former, there is significant curvature in the 20–80 K range. Also present in these two data sets are anomalies where the field changes at 20 and 10 K occurred.

The applied field of 15.0 G for the lower-temperature data is similar to fields employed in previous measurements of the initial susceptibility of $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$. For each crystal the susceptibility increased rapidly with decreasing T and then levelled off, characteristic behavior of a ferromagnet below T_c due to demagnetization effects. The corrected initial susceptibility χ_0 was analyzed using the critical law

$$\chi_0 = \Gamma t^{-\gamma}, \quad (1)$$

where $t=(T-T_c)/T_c$. As for earlier analyses of critical behavior in $\text{Fe}[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$, a maximum fitted temperature of 2.90 K was employed. The minimum temperature fitted was 2.459 K in each case. The results appear in Figs. 3 and 4, with parameters indicated. The fits are quite good, with rms deviations 0.91%, 0.97%, 0.95%, and 0.82% for $x=0.014_3$, 0.016_2 , 0.031_3 , and 0.040_2 , respectively. Data below 2.459 K exhibit transition rounding effects, and including them leads to serious deterioration in the fit. The precision of the fitted parameters is at the level or better of the last significant figures shown. Taking into account potential sources of absolute error, we estimate that the Γ are ± 0.03 emu/mol, the γ are ± 0.01 and the T_c are ± 0.003 K.

IV. DISCUSSION

In Fig. 5 is shown the ferromagnetic ordering temperature versus composition, earlier results for the pure material and the very weakly dilute crystal of Ref. 10 being included. In constructing this plot corrections to the T_c values in Figs.

FIG. 4. Critical law fits to initial susceptibility along [101] for $x=0.031_3$ and 0.040_2 single crystals of $\text{Fe}_{1-x}\text{As}_x[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$. For clarity the $x=0.040_2 \log \chi_0$ are shifted up 0.2. T_c is in K and Γ in emu/mol.

3 and 4 have been made. Independent critical region measurements, and analysis via Eq. (1), on the $x=0.014_3$ and 0.016_2 crystals were made using the same vibrating sample magnetometer (VSM) system employed in previous work (only these two crystals are large enough to measure in a small field on the VSM). The results implied that temperatures from the SQUID device were 0.017 ± 0.003 K higher, in the vicinity of 2.4 K, than those read by the carbon-glass resistance thermometer of the VSM system. The same VSM system yielded¹⁰ a $T_c = 2.453$ K for the pure material. This is 0.004 K lower than the accepted value of 2.457 K which was obtained independently from three different instruments previously. Hence the T_c in Figs. 3 and 4 have been reduced by 0.013 K, and Ref. 10 results have been increased by 0.004 K.

The variation of T_c with x is regular but, following an initial drop, rather weak. If the interval $x=0-0.0039$ can be taken as sufficiently small to approximate infinite dilution, then the characteristic quantity at this limit, $-(dT_c/dx)/T_c$, is 1.15 ± 0.11 , as noted previously.¹⁰ This is similar in size to the predictions 1.33 and 1.06 for the 2D square planar Ising and 3D simple cubic Ising models, respectively.⁹ No corresponding prediction for the dilute $Z_2 \times S_1$ model is available.

FIG. 5. Ferromagnetic ordering temperature and critical exponent γ vs composition in $\text{Fe}_{1-x}\text{As}_x[\text{S}_2\text{CN}(\text{C}_2\text{H}_5)_2]_2\text{Cl}$. Lines are guides to the eye only.

The weak dependence of T_c on x throughout most of the concentration range examined cannot be accounted for by correlated dilution,^{11,12} in which the coupling between nearest-neighbor magnetic ions depends on the state (magnetic versus nonmagnetic occupancy) of associated nearest-neighbor sites. Such effects have been shown to lead to "upward curvature" in T_c vs x plots. But this curvature appears at rather larger x (diluent) values than those spanned in this work. Moreover, the initial slope $-(dT_c/dx)/T_c$ is significantly enhanced, e.g., to 2.48 for the 2D square planar Ising model with strong correlation.¹¹

Although the variation of γ with x is not perfectly regular, it seems clear that a gradual increase occurs with increasing dilution. A change in critical behavior is predicted by the Harris criterion if $\alpha > 0$. Whether or not a continuous variation of critical exponents with dilution will occur may depend on the strength of the disorder.¹³ The increase in γ reported here is in the same sense as in simulations of the dilute 3D-Ising model.¹³ In the only studies we know of involving dilution of a definite $Z_2 \times S_1$ system, $\text{CsMn}_x\text{Mg}_{1-x}\text{Br}_3$,^{14,15} it was found that α decreased more or less continuously from 0.4 at $x=1$ to 0.2 at $x=0.95$,¹⁵ and β increased from 0.22 to 0.31 over the same range.¹⁴ From the scaling relation $\gamma = 2 - 2\beta - \alpha$, such variations would lead to an increase in γ of about 0.02. We may be seeing an analogous effect two or three times larger. The substantially smaller Γ for the two higher As crystals probably reflects increased disorder, as the $\chi^{-1}(T)$ behavior presumably does. Consequently less moment can be induced per unit field.

Magnetovolume effects of $\text{MnAs}_{1-x}\text{Sb}_x$

O. Nashima, T. Suzuki, and H. Ido

Department of Applied Physics, Tohoku Gakuin University, Tagajo, 985, Japan

K. Kamishima and T. Goto

Institute for Solid State Physics, University of Tokyo, Roppongi, Minato-ku, Tokyo, 106, Japan

Thermal expansion, high-field magnetization, and susceptibility measurements have been made for $\text{MnAs}_{0.7}\text{Sb}_{0.3}$. The thermal expansion measurements show that the spontaneous magnetostriction is large and anisotropic below T_c . The spontaneous magnetostriction at 0 K is estimated to be 1.2×10^{-2} for a axis, -0.8×10^{-2} for c axis, and 1.6×10^{-2} for the volume. The spontaneous magnetization decreases sharply in the narrow temperature region below $T_c = 230$ K. All the spontaneous magnetostrictions are found to be proportional to the square of spontaneous magnetization. The magnetization curves measured in a high field up to 40 T show the metamagnetic-like transitions at temperatures above T_c , and they are almost perfectly reproduced by an equation $H = A_1\sigma + A_2\sigma^3 + A_3\sigma^5$, where H is the applied field and σ is the relative magnetization. © 1996 American Institute of Physics. I. INTRODUCTION

It has been known that the mixed compound $\text{MnAs}_{1-x}\text{Sb}_x$ with $x \geq 0.1$ is a ferromagnet of hexagonal NiAs-type structure and has the large and anisotropic exchange magnetostriction.¹⁻³ The spontaneous magnetization decreases sharply in the narrow temperature region below the Curie temperature like a first-order transition. Magnetization curves at the temperatures above T_c show the field-induced magnetic transitions.^{1,2} These unusual characteristics were explained on the basis of the localized electron model.^{4,5} However, it is of no doubt that magnetic properties of this kind of intermetallic compounds have to be explained on the itinerant electron model.⁶ In the present work, we have carefully examined the magnetization process under a pulsed high magnetic field up to 40 T and the lattice parameters a and c by the x-ray diffraction technique on $\text{MnAs}_{0.7}\text{Sb}_{0.3}$. We have also measured the susceptibility of the compound at the

temperatures in a wide temperature range up to 1100 K. We discuss the results on the basis of the itinerant electron model.

II. SAMPLE PREPARATION

A mixture of powdered Mn, As, and Sb with more than 99.99% purity was heated at 800 °C in vacuum for 100 h to prepare the compound $\text{MnAs}_{0.7}\text{Sb}_{0.3}$. The crystal structure of the sample was confirmed by x-ray diffraction to be of the hexagonal NiAs type as shown in Fig. 1.

III. EXPERIMENTAL RESULTS

The temperature dependences of the lattice parameters a and c shown in Fig. 2 have been measured by the x-ray diffraction technique at the temperatures between 77 and 290 K. The normal thermal expansion of the c axis depicted by the dashed line is obtained by moving in parallel the thermal expansion of the c axis of MnSb , which shows no anomaly at the Curie temperature.⁷ The lattice parameters a and c show sharp increase and decrease, respectively, due to the ex-

FIG. 1. Crystal structure of the hexagonal NiAs type.

FIG. 2. Temperature dependences of lattice parameters of $\text{MnAs}_{0.7}\text{Sb}_{0.3}$.

FIG. 3. Temperature dependence of the unit cell volume of $\text{MnAs}_{0.7}\text{Sb}_{0.3}$. The inset shows the temperature dependence of the electric resistivity of strain gauge pasted on disk-shaped $\text{MnAs}_{0.7}\text{Sb}_{0.3}$.

change striction, with decreasing temperature at the Curie temperature. In Fig. 3, the unit cell volume V is plotted against the temperature. The normal thermal expansion shown by the dashed line is deduced by applying the Grüneisen relation⁸ to the temperature variation of the specific heat of MnAs. Temperature dependence of the electric resistance R of the strain gauge pasted on a disk-shaped polycrystal specimen is shown in the inset of Fig. 3. Since R has a linear relation with the thermal expansion of the specimen, the Curie temperature T_c is clearly determined to be 230 K, and the positive exchange striction shown in the inset agrees qualitatively well with the data by the x-ray diffraction. Temperature dependences of the spontaneous magnetostrictions $\omega_c = (c - c_0)/c_0$ and $\omega_v = (V - V_0)/V_0$ are obtained from the difference of the observed thermal expansion curves $c(T)$ and $V(T)$ and the normal thermal expansions $c_0(T)$ and $V_0(T)$ shown in Fig. 2 and Fig. 3, respectively. Temperature dependence of $\omega_v(T)$ and $\omega_c(T)$ are similar to each other except for their signs. Since $\omega_v = 2\omega_a + \omega_c$, $\omega_a(T)$ must be similar to $\omega_v(T)$ and to $\omega_c(T)$, by linear extrapolation to

FIG. 5. Temperature dependence of spontaneous magnetization of $\text{MnAs}_{0.7}\text{Sb}_{0.3}$.

$T=0$ K of $\omega_v(T)$ etc., we obtain the spontaneous magnetostrictions at $T=0$ K $\omega_a = 1.2 \times 10^{-2}$, $\omega_c = -0.8 \times 10^{-2}$, and $\omega_v = 1.6 \times 10^{-2}$.

As shown in Fig. 4, magnetization curves for $\text{MnAs}_{0.7}\text{Sb}_{0.3}$ have been measured in a pulsed magnetic field up to 40 T at various temperatures between 4.2 and 270 K. Field-induced magnetic transitions of the second order occur in the paramagnetic temperature region. The critical fields H_c which is defined as the inflection points of the magnetization curves are also shown in the inset. The saturation magnetic moment per Mn has been obtained to be $3.35\mu_B$ at 4.2 K, which is almost equal to the Mn moments of 3.4 and $3.57\mu_B$ in MnAs ⁹ and MnSb ,¹⁰ respectively. The spontaneous magnetizations M_s at temperatures between 180 and 230 K have been determined by applying the Arrott plot for the observed magnetization curves. In the range of $T \leq 200$ K, the linearity of M^2-H/M curves is good except for the range of $H/M < 0.05$ where the effects of magnetic domains may exist. However, in the temperature range of $200 \text{ K} < T < T_c$, M^2-H/M curves are not linear, hence M_s is estimated by the low-field part of the Arrott plot. The spontaneous magnetizations thus obtained are plotted against temperature in Fig. 5. It is noteworthy that the M_s decreases drastically in the temperature range just below $T_c = 230$ K. The temperature de-

FIG. 4. Magnetization curves of $\text{MnAs}_{0.7}\text{Sb}_{0.3}$ at the temperature of 4.2, 77, 180, 190, 200, 210, 220, 225, 230, 240, 250, 255, 260, and 270 K from top to bottom, respectively. The inset shows the temperature dependence of critical field.

FIG. 6. Temperature dependence of inverse susceptibility of $\text{MnAs}_{0.7}\text{Sb}_{0.3}$.

pendence of inverse susceptibility χ^{-1} is shown in Fig. 6. The melting temperature of the compound is about 1100 K. The χ^{-1} - T curve is out of straight line, and slightly convex upward, which implies a spin fluctuation effect,⁶ so magnetic moment $2S_{\text{Mn}}\mu_B$ (S_{Mn} : spin per Mn atom) has been estimated to be $3.9\mu_B$ by fitting the Curie Weiss law to the χ^{-1} - T curve between 600 and 800 K where the highest temperature region is below the melting point. In the liquid state ($T \geq 1100$ K), $4.3\mu_B$ is obtained. The paramagnetic Curie temperature is about -600 K for the liquid state.

IV. DISCUSSION

The large and anisotropic spontaneous magnetostrictions are shown in Fig. 2. In the Stoner model, the requirement of $I\rho(\epsilon_F) > 1$ is needed to stabilize ferromagnetism, where I is exchange interaction and $\rho(\epsilon_F)$ is the density of state at the Fermi energy. In general, I and $\rho(\epsilon_F)$ become large as the volume increases. So, positive ω_a and ω_v are reasonable, however, the negative large value of ω_c cannot be explained from the above point of view. Detailed calculation of the energy band structures is expected to explain the large and anisotropic ω_a and ω_c .

It is found that $\omega_v(T)$ and $\omega_c(T)$ and consequently $\omega_a(T)$ are proportional to the square of the spontaneous magnetization (M_s^2). When the coefficients α , β and γ are defined as $\omega_a = \alpha M_s^2$, $\omega_c = \beta M_s^2$, and $\omega_v = \gamma M_s^2$, we have obtained $\alpha = 7.1 \times 10^{-7}$, $\beta = -4.7 \times 10^{-7}$, and $\gamma = 9.5 \times 10^{-7}$ (emu/g)⁻². The temperature independent constant α , β , and γ are explained by the Bean and Rodbell model,⁴ if the interatomic exchange interaction depend on a and c axis separately. However, the Bean and Rodbell theory is not appropriate to this kind of compound which has characteristics of itinerant electrons such as that of MnAs etc. which were explained by Motizuki and Kato.⁶ So, the relation between ω_a etc. and M_s^2 mentioned above have to be explained on the basis of itinerant electron model.

We have analyzed the magnetization processes with the field-induced magnetic transitions at the temperatures above T_c by fitting the following equation to the experimental curves:

$$H = A_1(T)\sigma + A_2(T)\sigma^3 + A_3(T)\sigma^5, \quad (1)$$

where A_1 , A_2 , and A_3 are coefficients, H the applied magnetic field in units of Oe, and σ the relative magnetizations defined as $\sigma = M/M_s(0)$. According to the theory of metamagnetism by Yamada,¹¹ the parameters A_1 , A_2 , and A_3 in Eq. (1) are expressed by the following equations:

$$A_1(T) = \chi_p(T)^{-1} = a_1 + (5/3)a_2\xi_p(T)^2 + (35/9)a_3\xi_p(T)^4, \quad (2)$$

$$A_2(T) = a_2 + (14/3)a_3\xi_p(T)^2, \quad (3)$$

$$A_3(T) = a_3, \quad (4)$$

where a_1 , a_2 , and a_3 are constants and $\xi_p(T)^2$ is mean square of the spin fluctuation. The magnetization curves at the temperatures above T_c are perfectly reproduced by Eq.

FIG. 7. A_1 , A_2 , and A_3 vs T at the paramagnetic temperatures.

(1), and then $A_1(T)$, $A_2(T)$, and $A_3(T)$ have been obtained and plotted against temperature in Fig. 7. As shown in Fig. 7, A_1 varies almost linearly to the temperature, which is consistent with the temperature variation of inverse susceptibility. On the other hand, A_2 and A_3 are almost temperature independent. The result of A_3 is consistent with Eq. (4), however the temperature independent A_2 is difficult to explain. According to the Bean and Rodbell theory, A_1 increases linearly to the temperature and A_3 is temperature independent, however A_2 increases linearly to the temperature, so the temperature independent A_2 in Fig. 7 cannot be explained. The requirement for metamagnetic transition to occur is $3/16 < A_1 A_3 / A_2^2 < 9/20$, therefore if the linearity of A_1 keeps to 230 K, the requirement will be satisfied at 230 K. However, the magnetization curve at 230 K is not metamagnetic, probably because of the effects of short-range magnetic order. Metamagnetic transition will be realized if the Curie temperature is shifted to the lower temperature¹ by high pressure.

Transmission electron microscopy of Terfenol-D crystals

A. P. Holden, D. G. Lord, and P. J. Grundy

Physics Department, Joule Laboratory, University of Salford, M5 4WT, United Kingdom

Magnetic domain and microstructure observations are presented from samples of pseudo-single-crystal Terfenol-D examined by transmission electron microscopy (TEM). This ternary alloy is of significant technological interest since it exhibits the highest known magnetostriction to anisotropy ratio near room temperature. Specimens for TEM studies in (110), (111), and (112) orientations have also shown regions of unusual diffraction contrast in bright field which appears to be very sensitive to specimen tilt. Lorentz mode TEM has subsequently shown such regions to correspond exactly with magnetic domains. This contrast is attributed to the high magnetostrictive strain causing a local distortion of the lattice and thus a local deviation from the Bragg condition. This conclusion has been investigated and supported by TEM observations with the samples cooled below the spin reorientation temperature. When this transition is reached the diffraction contrast in bright field is considerably decreased and cannot be made to vary by tilting the specimen. The latter experiments also indicate that the change from $\langle 111 \rangle$ to $\langle 100 \rangle$ easy axis is not a well-defined one but, rather, that the spin reorientation is a sluggish change. High-resolution lattice images show the coherency of the twin boundaries. © 1996 American Institute of Physics. [S0021-8979(96)65808-6]

I. INTRODUCTION

This paper presents the results of magnetic domain and microstructure observations in samples of pseudo-single-crystal Terfenol-D ($\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2$) examined by transmission electron microscopy (TEM). This cubic Laves phase compound, which exhibits a giant positive coefficient of magnetostrictive strain (~ 2000 ppm along $\langle 111 \rangle$) coupled with a relatively low magnetocrystalline anisotropy ($K_1 \sim 10^5 \text{ J m}^{-3}$ at room temperature), is of current interest for device applications which utilize these properties. The work forms part of a general program which, using high-resolution TEM, optical microscopy, and scanning probe microscopy, is concerned with the investigation of the magnetization processes and magnetic domain/defect structure interactions in this unique material.

II. EXPERIMENT

Start material (obtained from Etrema Products in the form of 8-mm-diam rods) is produced using a free-standing-zone (FSZ) method. Such a preparation route has been previously shown¹ to have a dendritic growth front along the rod axis, $\langle 112 \rangle$, and to produce material with a high concentration of twin boundaries with the $\{111\}$ twinning plane orthogonal to the growth front. Thin disc samples with $(1\bar{1}0)$ and $(11\bar{2})$ orientations have been prepared for TEM observations, by spark erosion, mechanical dimpling and ion beam milling. Lorentz mode TEM observations were carried out using a JEOL 200CX TEMSCAN electron microscope equipped with a "field-free" objective lens. High-resolution lattice fringes have been obtained using a JEOL 3010 HRTEM.

III. RESULTS AND DISCUSSION

Figure 1(a) shows a near-focus bright-field micrograph obtained from a $(1\bar{1}0)$ orientation sample. Figure 1(b) shows a Foucault mode micrograph of the same area. Figure 1(c)

shows the same area near focus in bright field with the sample tilted slightly ($< 2^\circ$). In obtaining these micrographs the same objective aperture, positioned concentrically about the optical axis in the case of Fig. 1(a) and Fig. 1(c), was used and was of such a size that only the straight through beam was used to compose the image. In obtaining the micrograph shown in Fig. 1(c) the tilt position selected was that one where the obvious bright-field diffraction contrast could first be seen to such an extent. One can immediately see from a comparison of the three figures that the magnetic domains which are revealed in the Foucault mode can be easily discerned in the near-focus bright-field image [Fig. 1(c)] and that the contrast produced in bright field is comparable to that produced in the Foucault mode. Such effects have also been observed in (111) and $(11\bar{2})$ samples. Previous studies² of the domain structure in Terfenol-D by Lorentz TEM have also mentioned similar effects. The mechanism by which this contrast arises can be considered to be due to a local change in the reflecting conditions within the magnetic domains. Such a change can be brought about by giant magnetostrictive effects causing a change in the crystal lattice spacing thus altering the Bragg condition locally. Such changes can be quantified,³ in the light of the dynamical theory of image contrast, by calculating changes in the deviation parameter s . Such a change in s can be approximated by

$$\Delta s = \lambda_s \theta_B g,$$

where θ_B is the Bragg angle, λ_s is the magnetostrictive strain, and g is the reciprocal lattice vector for the operating reflection. Estimating the extinction distance ξ_g for Terfenol-D to be ~ 50 nm and λ_s to be 2000 ppm, one obtains an estimate for the product $\xi_g \Delta s$ of 5×10^{-3} . It can be shown³ that changes in $\xi_g \Delta s$ of this order of magnitude in alternate domains can lead to changes in intensity of $\sim 5\%$. It is therefore feasible that in materials which possess giant magnetostriction this property can lead to noticeable contrast effects in TEM (as it also has been shown to do in x-ray

FIG. 1. TEM micrographs revealing magnetic domains and bright-field diffraction contrast in a (110) orientation FSZ specimen showing (a) near-focus image, (b) Foucault contrast, and (c) near-focus image tilted to show bright-field diffraction contrast.

topography). We also note that for the changes in contrast commonly observed in this work ($\sim 10\%$) $\xi_g \Delta s$ would be approximately twice as large as that value calculated above. It might therefore be reasonable to assume that the magnetostrictive strain on the microscopic level is somewhat higher than that measured at the macroscopic level. In addition it should also be noted that Δs will increase (via increases in both g and ξ_g) for higher-order reflections.

When samples showing the diffraction contrast in bright field were cooled to 100 K, thus making $\langle 100 \rangle$ the easy direction, similar contrast effects to those shown in Fig. 1 were not observed. Since $\lambda_{111} \gg \lambda_{100}$ (Ref. 4) we might assume that the bright-field diffraction contrast, such as that shown in Fig. 1(c), is due to magnetostrictive distortion of the lattice.

Utilizing the change in features of Mössbauer spectra, previous workers⁵ have reported that $\langle 111 \rangle$ is easy down to approximately 273 K and that $\langle 100 \rangle$ is easy below ~ 175 K. In between these temperatures the easy direction was quoted as being intermediate. A later study⁶ based on the changes in characteristic x-ray diffraction data reported that the spin reorientation temperature lies in the range 263–273 K with $\langle 100 \rangle$ easy below this temperature range and $\langle 111 \rangle$ easy above it. Figure 2 shows a series of Fresnel out-of-focus

FIG. 2. Fresnel out-of-focus micrographs from (110) specimen obtained at (a) 273 K, (b) 230 K, and (c) 220 K.

micrographs obtained from a (110) sample. The micrograph shown in Fig. 2(a) was obtained at 273 K and the domain structure shown is identical to that which was observed at room temperature. Figure 2(b) shows a micrograph obtained from the same region with the sample temperature at 230 K. Figure 2(c) shows the same area as that shown in Fig. 2(b) at a temperature of 220 K. We note from these micrographs that the room-temperature domain structure is only just starting to change at 230 K and is almost completely gone at 220 K. We therefore report the occurrence of typical $\langle 111 \rangle$ easy axes patterns as low as 230 K and that the onset of the transition to $\langle 100 \rangle$ easy axes appears to occur at around 220 K. We also note that domain wall motion is still observed as low as 170 K. The transition thus appears to take place at a temperature lower than that most recently reported.⁶ Our studies also show that the transition from $\langle 111 \rangle$ to $\langle 100 \rangle$ easy axes shows some variability from sample to sample and even in different areas of the same sample. This suggests that magnetoelastic interactions and pinning effects are influential in determining the domain structure.

We have also made observations which focus on domain configurations in the vicinity of twin boundaries. This is mainly influenced by the results of previous² TEM investigations of Terfenol-D. In general the walls one observes in the vicinity of twin boundaries, in (110), are of 109° and 71°

character and arise due to out-of-plane components of magnetization. This is despite the existence of an in-plane easy direction, orthogonal to the twin boundaries, which is common to both parent and twin regions and would lead to 180° walls. The observed configurations require the twin boundary itself to be a domain wall which, if previous suppositions⁷ are correct, should be "frozen in." We have observed areas in which there are twin boundaries which show domain wall contrast at 293 K and then cooled the samples to ~ 100 K to see whether the twin boundary walls are mobile. A close examination and comparison of such domain patterns obtained at 293 and 100 K show that when the $\langle 100 \rangle$ easy axis pattern is adopted this is done in such a way that the twin boundary remains as a wall and therefore the associated domains must have walls consistent with such a scheme. Such domain configurations must arise from magnetization lying in the plane creating walls with 180° and 71° character. That such patterns are adopted in the vicinity of the twin boundary is indicative of the pinning action there. The latter observation is also supported from high-resolution TEM studies. When operating the JEOL 3010 HRTEM in high magnification mode the vertical field in which the sample sits is of the order of 2 T. Such a field easily suffices to saturate the samples and therefore magnetic domain wall contrast should not be seen. A comparison of areas observed using the JEOL 200CX and the JEOL 3010 HRTEM shows this to be the case except for those walls which lie along the twin boundaries. A HRTEM micrograph of a twin boundary is shown in Fig. 3 where lattice fringes can easily be seen. We also note from this micrograph the presence of some bands of contrast running in to the twin boundary in the $[110]$ direction as indicated on the figure. This is as yet unexplained and remains a feature of some interest given the direction and marked linearity of the features. If the twin boundary domain walls are frozen then it is evident that such high-resolution images have the potential to reveal much information regarding the magnetic coherence of the twin boundaries. This latter work forms part of an on-going programme concerned with the magnetoelastic properties of Terfenol.

IV. CONCLUSION

It has been shown that in materials exhibiting giant magnetostriction magnetic domains can be revealed by means other than Lorentz microscopy. This has been supported by quantitative considerations and by examining the material in

FIG. 3. HRTEM micrograph of twin boundary (TB) in $(\bar{1}10)$ specimen showing lattice fringes and further bright-field contrast effects.

a state where it no longer shows such giant magnetostriction. The spin reorientation process has been studied for the first time by means of TEM and the temperature at which this takes place has been shown to be slightly lower than that previously suggested. The domain wall pinning action at twin boundaries which also happen to be domain walls has been shown. High-resolution lattice fringes from twin boundary regions have been shown for the first time and show, as yet, unexplained contrast effects.

Propagation and reflection properties of magnetoelastic waves in $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$ amorphous wires are studied. The attenuation constant increases with increasing the driving frequency of the wave. As the attenuation constant of the wave driving at 500 kHz is quite small (0.18 m^{-1}), the wave is expected to be observed after the propagation of 20 or 30 m. As for the reflection, the magnetoelastic wave is reflected with the efficiency as much as 0.9 at the driving frequency below 2 MHz using a clamp as reflector. © 1996 American Institute of Physics. [S0021-8979(96)65908-2]

I. INTRODUCTION

Amorphous magnetic wires, such as FeSiB and FeCoSiB wires, provide attractive features including the magnetoelastic wave¹ and the magnetoimpedance effect.² Among them, it has been found that the magnetoelastic wave in FeSiB amorphous wire is well controllable and that it is suitable for sensors and the other applications. A large magnetostriction ($\lambda_s = 35 \times 10^{-6}$) in FeSiB realizes a large magnetoelastic coupling, and an efficient driving and pickup of the magnetoelastic wave. Due to the high electrical resistivity of amorphous FeSiB, an eddy current loss of the propagated magnetoelastic wave is low. Only a longitudinal mode of the magnetoelastic wave is propagated in the one-dimensional shape of the wires. Because of these characteristics, the attenuation constant of the magnetoelastic wave is low (0.18 m^{-1} at 500 kHz) and it is propagated through the long distance, which is applicable for the wide-range distance sensor.³ It detects a distance from 0 to 5 m with an accuracy less than 1 mm. In the sensor, sensitivity and resolution depend much on an attenuation constant and a reflection efficiency of the wave at the reflector. The experimental study of the propagation and reflection properties of magnetoelastic waves in FeSiB wire are reported.

II. EXPERIMENTS

Amorphous $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$ wires supplied from Unitika Co., Japan are used in this study. They are produced by the in-rotating-liquid spinning method.⁴ As-quenched wires of 125 μm in diameter are cold drawn to 90 μm . The as-drawn wires are magnetically hard. They have the following features: (1) a low efficiency to drive or to pick up the magnetoelastic wave, (2) a low attenuation of the magnetoelastic wave, (3) few interaction between the magnetoelastic wave and external magnetic and electric fields.

In order to realize the efficiency driving and pickup of the wave, small regions of the as-drawn wire are annealed by the partial annealing technique.¹ The annealing is performed by blowing a hot air from a nozzle connected with a ceramic heater (400 °C for 15 min without applying magnetic field). The annealed parts are magnetically soft and they are settled

at the positions of driving and pick-up coils as shown in Fig. 1. Bias coils surrounding the driving and pick-up coils are equipped in order to enhance an efficiency in driving and pickup of the wave. By applying a high-frequency current through the driving coil, the magnetoelastic wave is excited in the wire. The magnetoelastic wave excited by the high-frequency current of a tone-burst waveform is used for measurements of amplitudes of the wave. Details on driving and pickup of the wave have been reported.¹ The velocity of the wave is 4.7 km/s and its wavelength is about 1 mm at the driving frequency of 5 MHz.

III. RESULTS AND DISCUSSION

A. Propagation property

For the measurements of propagation property of the wave, the system shown in Fig. 1 is used. The amplitude of the wave propagated directly from the driving position and the amplitude of the wave propagated after reflecting at the reflector are measured by the pick-up coil, which are indicated as A_0 and A_1 in the figure, respectively. The ratio of A_1/A_0 is an attenuation ratio of the wave propagated for a length of x , where $x/2$ is a distance between the pick-up coil and the reflector. The reflection of the wave is performed by clamping the wire by a brass tool. The reflection efficiency as much as 0.8 is obtained by this method, which is discussed in the next section. Although the ratio of A_1/A_0 also includes an loss of the wave at the reflector, the measurement system shown in Fig. 1 is useful for the experiments of the propagation of the wave for a long distance. It is because the

FIG. 1. System for driving and pickup of the magnetoelastic waves and for measuring propagation and reflection properties of the waves.

FIG. 2. Measured amplitude ratio A_1/A_0 as a function of the propagation length of the magnetoelastic wave. The driving frequency of the wave is varied from 500 kHz to 4 MHz.

propagation length can be easily varied by changing the position of the clamp reflector without changing the position of the driving and pick-up coils. This technique is applied for the distance sensor.³

Figure 2 shows the measured amplitude ratio (A_1/A_0) indicated as a function of the propagation length up to 6 m. The driving frequency was varied from 500 kHz to 4 MHz. In the figure, the attenuation constant of the wave is obtained as a slope of the amplitude ratio against the propagation length. The intercept of the amplitude ratio where the propagation length equals to zero indicates a reflection efficiency of the wave at the reflector. With increasing driving frequency, the attenuation of the wave increases for the measured frequency range. It is because eddy current loss increases for a propagation of the high-frequency magnetoelastic wave. The wave driven at 500 kHz is propagated with a low attenuation constant of 0.18 m^{-1} , which corresponds to 8.6 dB for 10 m. It is expected to be observed with a sufficient-signal intensity after the propagation of 20 or 30 m.

B. Reflection property

The distance sensor using the magnetoelastic wave measures a distance between the driving/pick-up coil and the reflector by counting the propagation time of the wave. In order to obtain a sufficient signal intensity of the wave propagated through a long distance, an efficient reflection of the wave is required. Figure 3 shows the measured amplitudes of the wave propagated after the reflection (A_1 in Fig. 1) in the cases of $x=0.6, 2.0$, and 4.0 m, where x is the propagation length indicated in Fig. 1. The driving frequency of the wave is 1 MHz. As shown in the insertion in Fig. 3, the sample wire is clamped between pieces of brass material. It is found that the load of 5 N is required to obtain a sufficient reflection of the wave by the reflector used in this experiment. The frequency dependence of the reflection efficiency is also studied. As for materials of the clamp reflector, acrylic resin, stainless steel, and brass are studied. The load on the clamp is enough to obtain a maximum reflection in the measurement. As shown in Fig. 4, it is found that the reflec-

FIG. 3. Measured amplitudes of the reflected magnetoelastic wave as a function of the load on the clamp reflector. The driving frequency of the wave is 1 MHz. The insertion shows the reflector clamping the sample wire.

tion efficiency decreases with increasing the driving frequency of the magnetoelastic wave and that it is as much as 0.9 for the driving frequency below 2 MHz. The reflector of stainless steel has a high reflection efficiency in the high-frequency region above 2 MHz compared with that of brass, which is attributed to the large elastic constant of stainless steel. The figure also indicates the reflection efficiency for the acrylic resin reflector. The reflection of the wave is not observed for the driving frequency above 2 MHz. It is also found that when a soft urethane rubber is utilized as wave absorber shown in Fig. 1 the reflection efficiency is quite low.

Because the attenuation constant of the wave is small and the reflection efficiency is large for the wave driven at lower frequency, the frequency around 500 kHz is advantageous for applications such as the distance sensor. Although an accuracy of the distance sensor is high for the high driving frequency, the resolution as small as 1 mm, which is practically sufficient, is obtained at 500 kHz in the distance sensor having a detect range of 0–5 m.

FIG. 4. Reflection efficiency of the magnetoelastic waves as a function of the driving frequency. (●), (○), and (□) indicate the results for stainless steel, brass, and acrylic resin used as materials of the clamp, respectively.

IV. CONCLUSIONS

Propagation and reflection properties of the magnetoelastic waves in $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$ amorphous wires are studied. Due to a large magnetostriction of $\text{Fe}_{77.5}\text{Si}_{7.5}\text{B}_{15}$, efficient driving and pickup are obtained. The attenuation constant of the wave is measured at various driving frequency. With increasing frequency, the attenuation constant increases, which is due to an enhancement of eddy current loss. As the attenuation constant is quite small (0.18 m^{-1}) at 500 kHz, the wave is expected to be observed with a sufficient-signal intensity after the propagation of a long distance. The reflection effi-

ciency is also investigated. Using a clamp as reflector, the magnetoelastic wave is reflected with the efficiency as much as 0.9 for the wave driven below 2 MHz. These fundamental properties of the magnetoelastic wave are utilized to examine the device performance for devices such as the distance sensor.

In this contribution we present the results of direct measurements of the compressibility, in a wide temperature range, and studies of the linear thermal expansion under hydrostatic pressure using a modified strain gauge method in $\text{Ce}_3(\text{FeTi})_{29}$. A large magnetic contribution ($\kappa_m = 0.13 \text{ Mbar}^{-1}$) to the isothermal compressibility was observed in the ferromagnetic state in comparison with the compressibility in the paramagnetic state induced by pressure at room temperature. The pronounced lambda-shaped anomalies in the thermal expansion coefficient (negative values of α) and in the compressibility of the $\text{Ce}_3(\text{FeTi})_{29}$ compound were simultaneously observed in the vicinity of T_C .

I. INTRODUCTION

The $\text{R}_3(\text{FeTi})_{29}$ compounds belong to a family of iron-rich intermetallics (such as $\text{R}_2\text{Fe}_{14}\text{B}$ or $\text{RFe}_{12-x}\text{M}_x$) with outstanding properties for permanent magnet applications. These compounds crystallize in a monoclinical structure. X-ray and neutron diffractions were analyzed considering the space group $P2_1/c$ (Refs. 1–3) and A_2/m .⁴ The Curie temperatures T_C of the compounds are rather low, from 319 (R=Ce) to 520 K (R=Gd). However, the existence of a large magnetovolume coupling offers the possibility of increasing T_C by introducing interstitial atoms. Actually, this has stimulated an intensive study of both magnetic properties and magnetovolume effects in these compounds.

High-pressure experiments have revealed a significant influence of the volume changes on the magnetic interactions.^{5,6} A large spontaneous magnetostriction ω_S (Ref. 7) and an anomalous Invar-like behavior in the thermal expansion coefficient has been observed in the vicinity of T_C in the $\text{R}_3(\text{FeTi})_{29}$ compounds^{8,9} (R=Nd, Pr, Tb, and Gd). The discovery of the Invar phenomena in the $\text{R}_3(\text{FeTi})_{29}$ compounds⁷ enlarges the family of Invar materials. The large variation of T_C under pressure is considered as an important Invar characteristic that has been described within the band model of very weak itinerant ferromagnets by the well-known Wohlfarth's relation:¹⁰ $dT_C/dp \approx -A/T_C$, where A is constant within a wide temperature range in some Invar alloys ($A = 2200 \text{ K/kbar}$ for FeNi). The results obtained in $\text{R}_3(\text{FeTi})_{29}$ showed that the parameter A is constant and $A = 1200 \text{ K/kbar}$, along the series.¹¹ This is additional evidence of the existence of the Invar effects also in nearly strong itinerant systems.

Recently, we have measured the pressure dependence of the Curie temperature T_C on $\text{Ce}_3(\text{FeM})_{29}$ (M=Ti, Cr). A large decrease of T_C was observed under hydrostatic pressure up to 12 kbar for both compounds [$dT_C/dp = -3.75 \text{ K/kbar}$ for $\text{Ce}_3(\text{FeTi})_{29}$ and $dT_C/dp = -3.6 \text{ K/kbar}$ for $\text{Ce}_3(\text{FeCr})_{29}$].⁶ To correlate these pressure data with the spontaneous magnetostriction and other magnetovolume ef-

fects, we have performed compressibility measurements using a modified strain gauge method. In this contribution we present the results of direct measurements of the compressibility in a wide temperature range and studies of the linear thermal expansion under hydrostatic pressure.

II. EXPERIMENT

The polycrystalline sample was prepared by induction melting high-purity elemental constituents in a boron nitride crucible. The sample was annealed in vacuum for ten days at a temperature of 900 °C. X-ray diffraction and electron beam microprobe energy dispersed analytical x-ray (EDAX) analyses were carried out to monitor phase occurrences. The sample was found to be single-phase $\text{Ce}_3\text{Fe}_{27.4}\text{Ti}_{1.6}$. Crystallographic and magnetic information on this compound can be found in Ref. 12. The compressibility and the thermal expansion of the $\text{Ce}_3(\text{FeTi})_{29}$ compound was measured under pressure up to 8 kbar using strain gauges (Micro-Measurements Inc., SK-350) in the temperature range 100–550 K. The strain gauges were calibrated using as reference data the compressibility and thermal expansion of silica, Cu, and Fe. The pressure apparatus (made of a maraging steel) consists of two parts, a pressure generator and a pressure cell, both connected by a capillary. The pressure generator (with a manganic pressure sensor inside) was kept at room temperature. The temperature of the sample was measured using Thermocoax thermocouples inside the pressure cell.

III. RESULTS AND DISCUSSION

First studies of the changes of relative volume under pressure were made at room temperature. A decrease of the value of compressibility was observed for high pressures as well as a peak-like anomaly around 5 kbar. This can be related to the transition from the ferromagnetic to the paramagnetic state induced by pressure at room temperature. Figure 1 illustrates how the pressure range where the anomalous behavior of compressibility is observed at room temperature

FIG. 1. Pressure dependence of the ac initial magnetic susceptibility (○) and compressibility (Δ) of $\text{Ce}_3(\text{FeTi})_{29}$ at room temperature.

coincides with the transition of the sample from the ferromagnetic to the paramagnetic state as determined by susceptibility measurements. A similar behavior of the compressibility through a pressure-induced transition from ferromagnetic to paramagnetic state has recently been observed in $\text{Er}_2\text{Fe}_{14}\text{B}$.¹³

Figure 2 presents the linear thermal expansion and linear thermal expansion coefficient α for $\text{Ce}_3(\text{FeTi})_{29}$ at normal pressure and under a pressure of 5 kbar in the temperature range 240–400 K. The thermal expansion results are in rela-

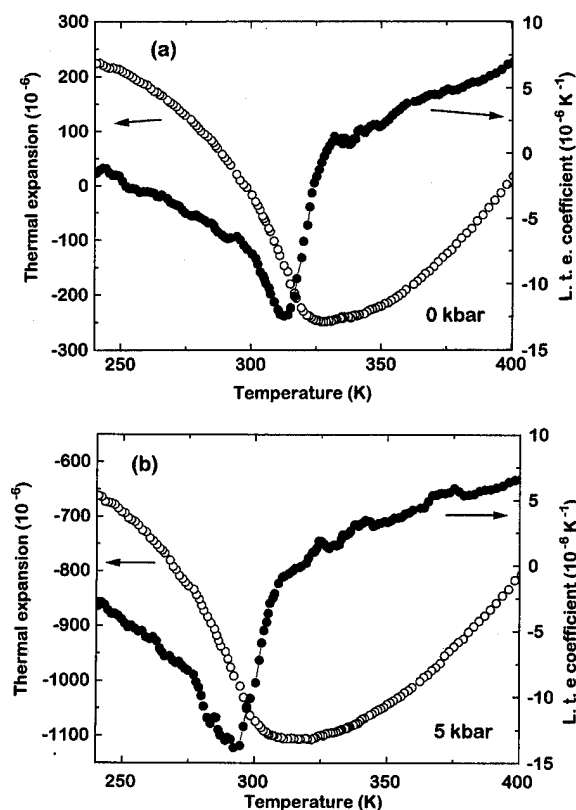

FIG. 2. Thermal dependence of the linear thermal expansion and the linear thermal expansion coefficient of $\text{Ce}_3(\text{FeTi})_{29}$ under (a) normal pressure and (b) under 5 kbar.

FIG. 3. Compressibility of the $\text{Ce}_3(\text{FeTi})_{29}$ compound in the vicinity of T_C at 2 kbar.

tion to ambient conditions (0 kbar, 295 K). A well-defined anomaly is observed at the magnetic ordering temperature T_C . The decrease of temperature of this anomaly corresponds to the decrease of T_C under pressure observed by Arnold *et al.*⁶

Figure 3 shows the temperature dependence of the compressibility $\kappa(T)$ of the $\text{Ce}_3(\text{FeTi})_{29}$ compound. It is worth noting that the compressibility has a maximum followed by a steep decrease near T_C . This behavior of the compressibility reflects some softening of the crystal lattice within the ferromagnetic state and during the transition from the ferromagnetic to the paramagnetic state. If we compare the compressibility values at temperatures well above and below T_C (± 50 K), we can estimate that the magnetic contribution to the compressibility is $\kappa_m = 0.13 \text{ Mbar}^{-1}$.

Figure 4 presents the temperature dependencies of the bulk modulus $B = 1/\kappa$ determined at 2 kbar and the linear thermal expansion coefficient α for the $\text{Ce}_3(\text{FeTi})_{29}$ compound. Both quantities exhibit pronounced lambda-shaped anomalies in the vicinity of T_C . Such behavior is not typical for Invar alloys. The studies of the anomaly of the bulk modulus of Invar Fe-Ni alloys and disordered Fe_3Pt alloys

FIG. 4. Thermal dependence of the linear thermal expansion coefficient and bulk modulus in the vicinity of T_C for $\text{Ce}_3(\text{FeTi})_{29}$.

showed that the anomalies of elastic constants around T_C on Invar Fe-Ni alloys are very smooth and spread through several hundred degrees.^{14,15}

The relatively high value of the compressibility for $\text{Ce}(\text{FeTi})_{29}$ in the ferromagnetic state, $\kappa=1.22 \text{ Mbar}^{-1}$, has another consequence. The volume derivative $dT_C/d \ln V$ has a value of 3100 K, which is the same as was observed for the $\text{Nd}_3(\text{FeTi})_{29}$ compound⁵ within the experimental error. From this result one can conclude that the volume dependence of the exchange interaction is identical for both $\text{Ce}_3(\text{FeTi})_{29}$ and $\text{Nd}_3(\text{FeTi})_{29}$ compounds, although their T_C differs by 100 K (25%). Similar behavior of volume derivatives $dT_C/d \ln V$ was revealed for several Fe-rich Nd-based intermetallics.¹⁶

Recently, the nitrides $\text{Ce}_3(\text{FeTi})_{29}\text{N}_x$ were prepared and both the increase of interatomic distances and increase of T_C caused by nitration were found to be the highest in the whole family of the $\text{R}_3(\text{FeTi})_{29}$ compounds.¹⁷ Using the value of $dT_C/d \ln V$, we can estimate that an increase in volume of 1% will produce an increase of 31 K in T_C in $\text{Ce}_3(\text{FeTi})_{29}$. As the nitration causes an increase in volume of 6.96% in this compound we can expect an increase in T_C of about 220 K because of an increase in volume. However, in the nitrogenated compound an increase of 340 K in T_C has been found ($T_C=670 \text{ K}$). This comparison clearly shows, as was observed in Mössbauer experiments,¹⁸ that not only the lattice expansion but also the electron transfer to the N atoms is relevant in the magnetic behavior in interstitial $\text{R}_3(\text{FeTi})_{29}$ compounds. A similar behavior was observed in pressure experiments in R_2Fe_{17} compounds.¹⁹

We can conclude that a large magnetic contribution ($\kappa_m=0.13 \text{ Mbar}^{-1}$) to the isothermal compressibility was observed in the ferromagnetic state in comparison with the compressibility in the paramagnetic state of the $\text{Ce}_3(\text{FeTi})_{29}$ compound. Pronounced lambda-shaped anomalies in the thermal expansion coefficient and in the compressibility of $\text{Ce}_3(\text{FeTi})_{29}$ were simultaneously observed in the vicinity of T_C . The volume dependence of the exchange interaction of the $\text{Ce}_3(\text{FeTi})_{29}$ compound is the same as in Fe-rich Nd-based intermetallics.¹⁶

We report high-field magnetostriction and thermal expansion measurements in $\text{FeRh}_{1-x}\text{Pt}_x$ ($x=0.75, 0.765$, and 0.7) compounds. From the thermal expansion measurements we have observed the para-ferromagnetic and ferro-antiferromagnetic transitions for $x=0.75$ and 0.765 , and the para-antiferromagnetic transition in the 0.7 compound. The volume expansion associated with the first-order transitions has been determined. The results of the magnetostriction measurements are complex and are explained here on the basis of an induced transition from an antiferromagnetic to a ferromagnetic state, induced by the applied magnetic field. © 1996 American Institute of Physics. [S0021-8979(96)66108-0]

I. INTRODUCTION

In some recent works^{1,2} we have reported a huge positive volume magnetostriction and a giant magnetoresistance³ at and above room temperature in cubic bcc FeRh and FeRh-Pd alloys. Such effects are related to the ferro-antiferromagnetic (F-AF) phase transition observed in these alloys, which is accompanied by a large magnetovolume effect and a change in the magnetic moment of the Rh from $\approx 1 \mu_B$ in the F phase to $0 \mu_B$ in the AF phase.⁴

The substitution of Rh by Pt in the FeRh system is effective in stabilizing the tetragonal bct phase in a wide range of Pt concentrations.⁵ Bct $\text{FeRh}_{1-x}\text{Pt}_x$ alloys are therefore suitable for investigating the influence of the crystalline structure on the magnetic properties of the FeRh-based alloys. The most interesting property of the bct alloys is the first-order phase transition from the low-temperature AF state to the high-temperature paramagnetic (PM) or F state.^{5,6}

Bct $\text{FeRh}_{1-x}\text{Pt}_x$ with $0.81 \leq x \leq 1$ is a simple ferromagnet, while bct alloys with $0.72 \leq x \leq 0.81$ are antiferromagnetic at low temperatures and undergo a first-order AF-F transition with increasing temperature. This transition is accompanied by a reduction in the lattice parameter a and an increase along c . In the case of $x=0.8$ the changes in the lattice parameters a and c were -0.3% and $+0.75\%$, respectively, giving a volume expansion of $+0.15\%$ and an increase in the axial ratio c/a of 1.05% . In the composition range $0.3 \leq x \leq 0.72$ a direct transition from a low-temperature AF state to a high-temperature PM state is observed in the $\text{FeRh}_{1-x}\text{Pt}_x$ alloys. This transition is also a first-order transition with a volume expansion of $+0.15\%$ and an increase in the axial ratio c/a of $+0.36\%$ in the case of $x=0.7$ (see the phase diagram of this series of alloys in Ref. 5).

In this work the spontaneous and field-induced magnetovolume effects on the $\text{FeRh}_{1-x}\text{Pt}_x$ alloys were studied by

performing linear thermal expansion (LTE) and magnetostriction measurements.

II. EXPERIMENT

The samples were prepared by a plasma jet melting from pure Fe (4N), Rh (3N), and Pt (4N) in an argon atmosphere. Details of sample preparation can be found in Ref. 5. Magnetization measurements were performed in order to characterize the magnetic transitions, using a pendulum-type magnetometer with an applied magnetic field of 6 kOe. Thermal expansion measurements were obtained using a "push-rod" based dilatometer in the temperature range 150–500 K. The magnetostriction experiments were carried out using the strain-gauge technique, under high-pulsed magnetic field up to 15 T with a pulse width of 50 ms.

III. RESULTS AND DISCUSSION

A. Thermal expansion

The results of linear thermal expansion experiments for the different compounds are shown in Fig. 1. For the compounds with $x=0.75$ and 0.765 three magnetic regions are observed in the studied temperature region (Figs. 1(a) and 1(b)). The first one is $T > 450$ K and corresponds to the paramagnetic state. The temperature region $350 > T > 450$ K (for $x=0.75$) and $300 > T > 450$ K for ($x=0.765$) corresponds to the ferromagnetic phase. For lower temperatures an AF ordering appears. The temperatures at which the different magnetic phase transitions take place are indicated by the anomalies observed in the LTE coefficient, α (see Fig. 1). The longitudinal spin fluctuations (Stoner excitation, proportional to the square of the local magnetic moment) and transverse spin fluctuations (spin-wave excitations) are responsible for the extra contribution to the LTE (also called the Invar effect).⁷ Due to the low value of this extra contribution in the PM to F phase transition, the transverse spin fluctuations of magnetic moments could be the origin of such a change.

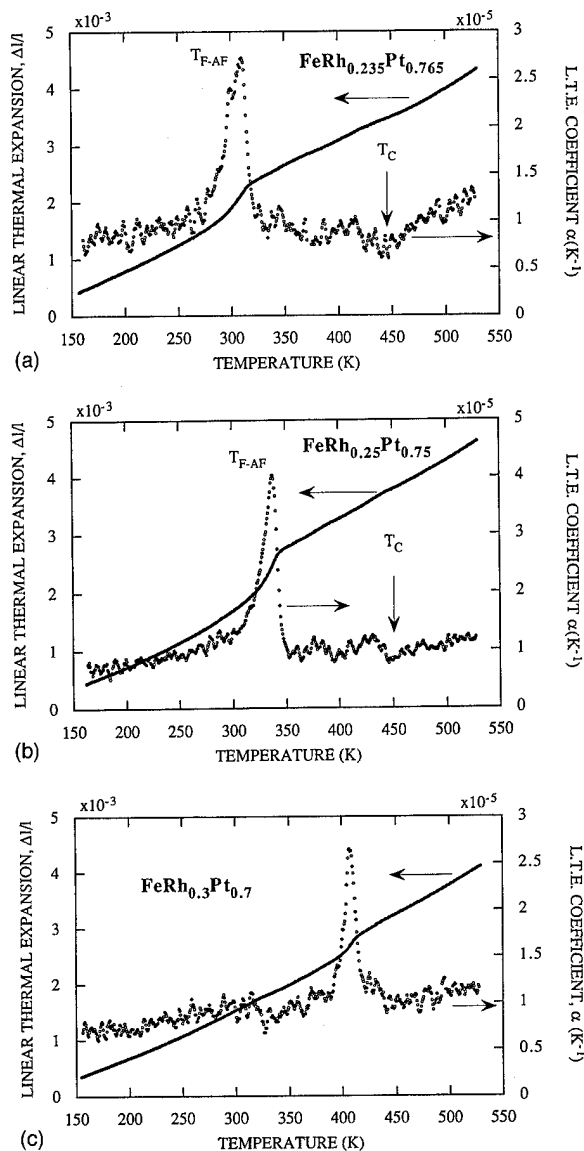

FIG. 1. Linear thermal expansion (LTE) and LTE coefficient α for the $\text{FeRh}_{1-x}\text{Pt}_x$ alloys, (a) $x=0.75$, (b) $x=0.765$, and (c) $x=0.7$.

The F-AF phase transition (at $T_{\text{F-AF}}$) is accompanied by a very large and sharp drop in the LTE and a volume change ($\omega = \Delta V/V = 3\Delta l/l$) of 0.15% for both compounds [see Figs. 1(a) and 1(b)]. In this transition transverse spin fluctuations do not play any role because the transition starts in the F phase and therefore, the large spontaneous extra contribution to the LTE could be ascribed to the longitudinal spin fluctuations. Although an experimental determination of the magnetic moment in the different phases does not exist, a theoretical band calculation performed in the isostructural $\text{FeRh}_{1-x}\text{Pd}_x$ alloys obtained a local magnetic moment of $\mu_{\text{Fe}} = 3.1\mu_B$, $\mu_{\text{Rh}} = 0.69\mu_B$, and $\mu_{\text{Pd}} = 0.32\mu_B$ in the F state, and $\mu_{\text{Fe}} = 3.15\mu_B$ and $\mu_{\text{Rh}} = \mu_{\text{Pd}} = 0\mu_B$ in the AF state, with a larger volume in the F state.⁸ Therefore, such spontaneous magnetostriction can be ascribed to the collapse of the Rh and Pt local magnetic moment within the AF phase, and this behavior can be accounted for within the framework of the Invar effect, as in the case of the FeRh and FeRhPd alloys.

It is worth remarking that in the case of the cubic alloys the spontaneous magnetostriction associated with the F-AF transition is isotropic (only volume changes) but in the case of the bct alloys the spontaneous magnetostriction has an anisotropic character with a change in the c/a ratio in the F-AF transition as has been mentioned before.

From our LTE measurements performed on polycrystalline samples only the spontaneous volume magnetostriction can be obtained. The volume change, determined from our experiments, associated with the F-AF transition is $\approx 0.15\%$ for both samples. This is in good agreement with the results from x-ray experiments.⁵

For the $\text{FeRh}_{0.3}\text{Pt}_{0.7}$ alloy [see Fig. 1(c)] only one transition from PM to AF state is observed at $T_{\text{PM-AF}} \approx 405$ K. The large extra contribution to the LTE associated with this phase transition ($\omega \approx 0.15\%$) suggests that both contributions,

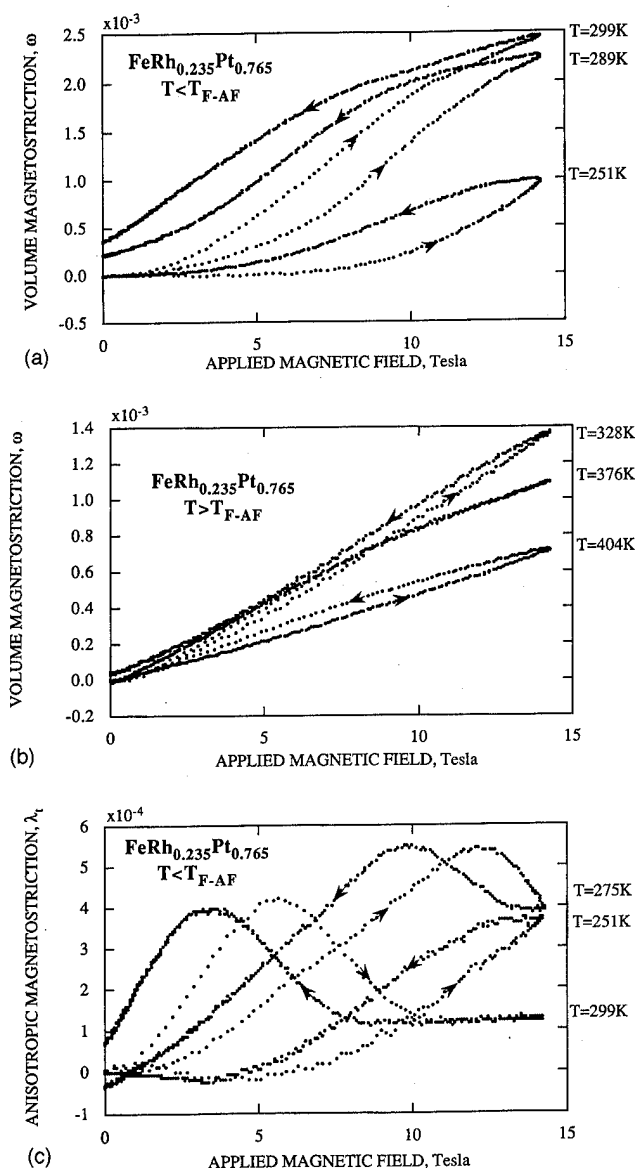

FIG. 2. Isotherms of the volume (ω) and anisotropic (λ_i) magnetostriction vs applied magnetic field of the $\text{FeRh}_{0.235}\text{Pt}_{0.765}$ compound, (a) ω in the AF state, (b) ω in the F state, (c) λ_i in the AF state.

FIG. 3. Isotherms of the volume magnetostriction vs applied magnetic field of the $\text{FeRh}_{0.3}\text{Pt}_{0.7}$ alloy.

longitudinal and transverse spin fluctuations, are relevant in the PM-AF phase transition.

B. Magnetostriction

Parallel (λ_{\parallel}) and perpendicular (λ_{\perp}) magnetostrictions, to the applied magnetic field, were measured using high-pulsed magnetic fields. From these experimental measurements the anisotropic ($\lambda_t = \lambda_{\parallel} - \lambda_{\perp}$) and volume ($\omega = \lambda_{\parallel} + 2\lambda_{\perp}$) magnetostriction were obtained.

In Fig. 2 we present the results obtained for the $\text{FeRh}_{0.235}\text{Pt}_{0.765}$ alloy, as representative of the compounds with F and AF states. The volume magnetostriction isotherms in the AF state are shown in Fig. 2(a). For the lowest measured temperature ($T=251$ K), ω is almost zero for low magnetic fields and starts to increase at $H \approx 10$ T. At higher temperatures (near the F-AF transition temperature) the isotherms present a similar behavior, but the increase of magnetostriction takes place at lower magnetic fields. At high magnetic fields the slope changes, becoming constant (see for instance the isotherm at $T=299$ K). Such behavior can be explained considering that the applied magnetic field is able to induce the AF-F transition, which starts when the magnetostriction increases, and that the F state is reached at the change of the slope. A large hysteresis of about 3 T is observed in the field induced transition. The change of slope at high magnetic fields corresponds to the linear magnetostriction observed in the F state [see Fig. 2(b)]. Such behavior is completely different to that observed in the cubic com-

pounds, in which the volume magnetostriction observed in the F state was nearly zero. Such difference can be ascribed to the different crystallographic structure of both compounds.

In the anisotropic magnetostriction results in the AF state we observed a complex behavior, with the appearance of a maximum at a determined magnetic field, which corresponds to the magnetic field needed to induce the F state [see Fig. 2(c)]. In the F state a negligible anisotropic magnetostriction is observed.

The situation in the $x=0.7$ compound is different. In this alloy only one transition corresponding to a first-order P to Af phase transition at $T_{\text{PM-AF}} \approx 407$ K takes place [see Fig. 1(c)]. The experimental results obtained for the volume magnetostriction are presented in Fig. 3. The behavior of the isotherms is similar to the lower-temperature isotherms for the $x=0.765$ compound in the AF state. In this state zero magnetostriction is obtained at low magnetic field and starts to increase at some particular value of the applied magnetic field. This value of the magnetic field decreases as the temperature increases, approaching the critical temperature of the PM-AF phase transition. Such behavior suggests a possible transition from the AF to a F metastable state, which is not thermally reached, but could be obtained by an applied magnetic field higher than our maximum available field. As in the case of the $x=0.765$ alloy the anisotropic magnetostriction is negligible.

Magnetostriction of a superconductor: Results from the critical-state model

Z. Koziol^{a)} and R. A. Dunlap

Department of Physics, Dalhousie University, Halifax, Nova Scotia B3H 3J5, Canada

In many cases, the critical-state theory can be treated as a sufficiently accurate approximation for the modeling of the magnetic properties of superconductors. In the present work, the magnetostrictive hysteresis is computed for a quite general case of the modified Kim–Anderson model. The results obtained reproduce many features of the giant magnetostriction (butterfly-shaped curves) reported in the literature for measurements made on single-crystal samples of the high-temperature superconductor $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$. It is shown that the addition of a contribution to the magnetostriction in the superconducting state which is of similar origin as in the normal state, offers a broader phenomenological interpretation of the complex magnetostriction hysteresis found in such heavy-fermion compounds as UPt_3 , URu_2Si_2 , or UBe_{13} . © 1996 American Institute of Physics. [S0021-8979(96)66208-X]

I. INTRODUCTION

Measurement of the magnetization has been the most commonly used experimental technique for the study of flux pinning. Recently, however, magnetostriction studies have been shown informative. For example, Ikuta *et al.*¹ observed a giant magnetostriction in $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$ single crystals in the superconducting state and showed that the largest contribution to this effect comes from the interaction between the critical currents induced by changing the external field and the applied field, i.e., the Lorentz force. Much attention has also been directed to dilatometry studies of heavy-fermion superconductors. In UPt_3 ,² the irreversible contribution to the magnetostriction is small but in UBe_{13} ,³ UPd_2Al_3 ,⁴ and URu_2Si_2 ,⁵ large sample size changes are observed.

In large fields, when the magnetic induction B changes negligibly across the sample (e.g., in URu_2Si_2 , for $H \geq 10^3$ Oe,⁶ the idealized situation for a slab of thickness $2D$ may be written as $B(x) \approx H - (4\pi/c)j_c(D-x)$, with $x=0$ at the center of the slab. Here, H is the external magnetic field and j_c is the critical current density, $(4\pi/c)j_c = -dB/dx$. The local Lorentz force exerted on the current carriers, $f = (1/c)j_c B(x)$, is directed towards the center of the sample and leads to its compression, for increasing external field. This force must be compensated by the internal local stress, $\sigma(x)$; $\partial\sigma/\partial x = (1/c)j_c B(x)$. Hence, with $j_c = -(c/4\pi)dB/dx$, we find that $\sigma(x) = -[H^2 - B^2(x)]/8\pi$, for the boundary condition $\sigma(D) = 0$. For a material characterized by the elastic constant c_{11} , the relative change of the sample size, $\Delta D/D$, is given by

$$\frac{\Delta D}{D} = \frac{1}{D} \int_0^D \frac{\sigma(x)}{c_{11}} dx, \quad (1)$$

which is equal to $-1/(8\pi c_{11}D) \int_0^D [H^2 - B^2(x)] dx$. For the present case, with $(c/4\pi)j_c \ll B/D$, we have: $\Delta D/D \approx -f_p/(2c_{11})D$. Hence, $\Delta D/D$ is directly related to the flux-pinning force density, $f_p = (1/c)Bj_c$.

II. MAGNETOSTRICTION IN THE MODIFIED KIM–ANDERSON MODEL

For qualitative calculations, we shall consider the simplest possible geometry: a slab of thickness $2D$, with the external magnetic field H applied along its surface. We use a modified Kim–Anderson formula for defining the critical current density, $j_c(B)$, corresponding to a local gradient of the magnetic induction:

$$j_c = \alpha/(B+h)^n = -(c/4\pi)dB/dx. \quad (2)$$

This dependence unifies many forms of the critical state models. The calculating the magnetization for this geometry and for $j_c(B)$ given by Eq. (2) can be found in Ref. 7. This previous work⁷ contains an analysis of other effects observed in superconductors which can be explained using the model of a critical state. The present work provides additional explanation of these phenomena and may be considered as a continuation of our work on this subject.

The calculation of the magnetostriction consists of: (i) finding the magnetic field distribution during the magnetization process, (ii) integrating the equation $\partial\sigma/\partial x = (1/c)j_c B(x)$ with the boundary condition that $\sigma(D) = 0$, and (iii) using Eq. (1) for calculation of the magnetostriction. The solution of Eq. (2) determines the flux distribution and has the form: $B(x) = [\pm(4\pi/c)\alpha(n+1)x + \beta]^{1/(n+1)} - h$, where the integration constant β is determined from the boundary condition $B(\pm D) = H$, with the sign of $dB(x)/dx$ dependent on the most recent field change direction occurring at point x . For the virgin magnetization curve, β is given by: $\beta = (H+h)^{n+1} - H_m$, where $H_m = (H^*+h)^{n+1} - h^{n+1}$, and H^* is the field of the first full flux penetration into the center of the slab, $H^* = [\alpha(n+1)D + h^{n+1}]^{1/(n+1)}$. Some examples of the flux distribution for different situations are drawn schematically in Fig. 1. In this figure, B_0 is the magnetic induction in the sample center and is given in Table I for various stages of the magnetization process. The magnetostriction during the virgin magnetization process, for $H < H^*$, is found to be

$$\frac{8\pi c_{11}\Delta D(H)}{D} = H^2 - \frac{1}{H_m} \left\{ h^2[(H+h)^{n+1} - h^{n+1}] \right\}$$

^{a)}Electronic mail: zkoziol@is.dal.ca; http://is.dal.ca/~zkoziol/zkoziol.html

FIG. 1. The magnetic induction distribution in a sample volume when (a) field increases from 0 to $H < H^*$, (b) field increases to $H > H^*$, (c) and (d) when field decreases from H_{\max} to H , and (e) when field decreases below 0. B_0 is the field at the slab center. B_v is the field at the kink of the flux distribution at x_v , occurring for a certain range of H values after the sweep direction of H is changed. x_v is equal to $1 - [(H_{\max} + h)^{n+1} - (H + h)^{n+1}]/(2H_m)$. B_v and B_0 are defined in Table I.

$$+ (n+1) \left\{ \frac{(H+h)^{n+3} - h^{n+3}}{n+3} - 2h \frac{(H+h)^{n+2} - h^{n+2}}{n+2} \right\}. \quad (3)$$

In order to provide the results for the entire magnetization loop in a transparent form, we define the following quantities:

$$\begin{aligned} F_{i,1}(H_{i,-}, H_{i,+}) &= h^2 [(H_{i,+} + h)^{n+1} - (H_{i,-} + h)^{n+1}] / H_m, \\ F_{i,2}(H_{i,-}, H_{i,+}) &= -(n+1)/(n+2) 2h [(H_{i,+} + h)^{n+2} - (H_{i,-} + h)^{n+2}] / H_m, \\ F_{i,3}(H_{i,-}, H_{i,+}) &= (n+1)/(n+3) [(H_{i,+} + h)^{n+3} - (H_{i,-} + h)^{n+3}] / H_m, \end{aligned}$$

with $H_{i,-}$ and $H_{i,+}$ defined in Table I, for situations corresponding to those in Fig. 1. The index i enumerates different branches of the magnetic induction curves of continuous $j_c(x)$ dependence. Using the above equations, the magnetostriction can be written as

$$8\pi c_{11} \Delta D(H)/D = H^2 - \sum_{i=1,2} f(H_{i,-}, H_{i,+}), \quad (4)$$

where

$$f(H_{i,-}, H_{i,+}) = S(H_{i,-}, H_{i,+}) [F_1(H_{i,-}, H_{i,+})$$

TABLE I. Characteristic fields corresponding to the curves (a) to (e) in Fig. 1. B_v is equal to $\{0.5[(H_{\max} + h)^{n+1} + (H + h)^{n+1}]\}^{1/(n+1)} - h$.

Case	$H_{0,-}$	$H_{0,+}$	$H_{1,-}$	$H_{1,+}$
a	0	H	0	0
b	$B_0 = [(H+h)^{n+1} - H_m]^{1/(n+1)} - h$	H	0	0
c	$B_0 = [(H_{\max} + h)^{n+1} - H_m]^{1/(n+1)} - h$	B_v	B_v	H
d	$B_0 = [(H+h)^{n+1} + H_m]^{1/(n+1)} - h$	H	0	0
e	$B_0 = [-(H + h)^{n+1} + (H^* + h)^{n+1} + h^{n+1}]^{1/(n+1)}$	0	0	H

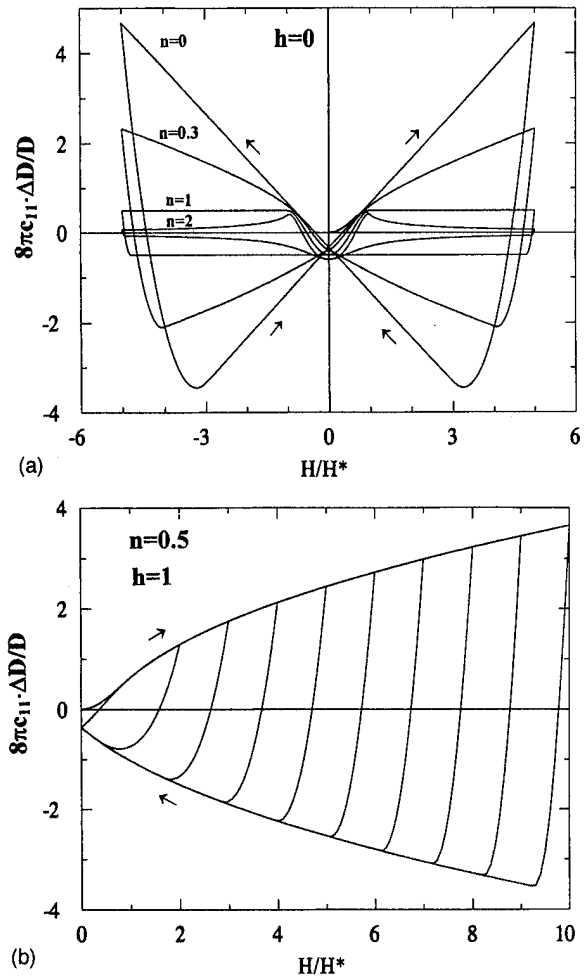

FIG. 2. The calculated magnetostriction curves, the virgin one and the entire hysteresis loop; (a) $h=0$, while n changes from 0 (the Bean model) to $n=2$, (b) when $n=0.5$, $h=1$ while H_{\max} ranges between 2 and 10. The arrows indicate the direction of field change.

$$+ F_2(H_{i,-}, H_{i,+}) + F_3(H_{i,-}, H_{i,+})]. \quad (5)$$

The function $S(H_{i,-}, H_{i,+})$ in Eq. (5) is equal to +1 when $H_{i,-} \leq H_{i,+}$ and to -1, otherwise. The remaining part of the magnetostriction hysteresis curve, not covered in the Table I, may be computed using symmetry: $\Delta D(-H) = \Delta D(H)$.

Some examples of the calculated magnetostriction hysteresis curves are shown in Fig. 2. A large variety of $\Delta D(H)$ dependences is found: from $\Delta D(H)$ proportional to H at $H > H^*$, when $n=0$ (Bean model), to $\Delta D(H)$ strongly suppressed by field when $n > 1$. For $n > 0$, an abrupt passing through $\Delta D(H) = 0$ is found, when the field sweep direction changes. The field width of this transition region decreases strongly with an increase of the maximum field applied [Fig. 2(b)]. This is due to a low value of the critical current density at large fields and a decrease in the field change required to reverse the direction of current flow in the sample volume. A significant remanent magnetostriction due to a frozen-in magnetic field is observed. The features discussed above are commonly observed for high- T_c and heavy-fermion superconductors.

FIG. 3. The calculated magnetostriction curves for $n=0$ (the Bean model) for several values of the parameter G , determining the normal-state contribution to the magnetostriction: $G=2, 1, 0, -1$, and -2 , for curves from top to bottom, respectively. One must note that the values of G depend on the units of the magnetic field assumed, which are here equal to H^* . The vertical scale has been shifted for some curves, for better clarity. The arrows indicate the direction of field change.

An unusual effect has been observed recently⁵ for single crystal of URu_2Si_2 . For fields near the upper critical field, $H_{c2}(T)$, the irreversible contribution to the magnetostriction changes sign compared to the sign observed at lower fields. Moreover, it was observed⁵ that the sign of the irreversible contribution to the magnetostriction for some experimental configurations disagreed with the prediction of the critical-state model. On the other hand, a large background contribution to the magnetostriction, $\Delta D/D = bB^2$, with the parameter b of the order of $10^{-16}/G^2$, has been reported for heavy-fermion materials,^{2,3,5} which is apparently of the same origin as the normal-state magnetostriction. The role of this contribution on the overall shape of the magnetostriction may be considered. We note that the critical-state magnetostriction component results from the calculation of an integral over the $B^2(x)$ dependence. The total magnetostriction in the superconducting state is then assumed to be the sum of the critical state and the normal-state-like components. The sign of both contributions must be considered carefully. The critical-state magnetostriction depends on the sign of the magnetic field and current while the normal-state contribution depends on the sign of the coefficient b . Using these arguments, we may write

$$8\pi c_{11}\Delta D(H)/D = H^2 - \sum_{i=1,2} [f(H_{i,-}, H_{i,+}) - G|f(H_{i,-}, H_{i,+})|], \quad (6)$$

with $f(H_{i,-}, H_{i,+})$ given by Eq. (5) and $G = 8\pi c_{11}b$. Magnetostriction calculated from Eq. (6) for a few values of the parameter G is shown in Fig. 3. An important feature of these results is that both signs of the magnetostriction and both

signs of the irreversible contribution to the magnetostriction hysteresis are possible, while the shape of the curves might only be weakly affected by the presence of a normal-state contribution (except for the presence of a large background proportional to H^2). The hysteresis of the normal-state-like contribution to the magnetostriction in the superconducting state is due to inhomogeneity of the magnetic induction across the sample volume, which is caused by the presence of critical current. It is easy to show that at large fields, in particular, near the upper critical field, both contributions to the irreversible magnetostriction are proportional to the critical current density. Hence, the most intriguing property of the magnetostriction in some heavy-fermion superconductors, i.e., the change of sign of the irreversible part of the magnetostriction as a function of the applied field, cannot be explained by this model, if it is assumed that the parameter G in Eq. (6) is independent of the magnetic field value.

Using Eq. (5), magnetic measurements⁶ in conjunction with the value of the elastic constant c_{11} allow for a determination of $\Delta D/D$. In URu_2Si_2 , $c_{11} = 2.4 \times 10^{12} \text{ erg/cm}^3$,⁸ yields $2\Delta D/D = 3.6 \times 10^{-8}$ and $2\Delta D/D = 6 \times 10^{-8}$, for $H//c$ and $H//a$, respectively, in reasonable agreement with measured properties.⁵ On the other hand, for UPt_3 , the elastic constant is larger, about $6 \times 10^{12} \text{ erg/cm}^3$,⁹ and the critical current density is much lower,⁷ resulting in an irreversible contribution to the magnetostriction which is hardly observable experimentally.

Gloos *et al.*⁴ reported significant difference between the thermal-expansion curves measured during cooling in a magnetic field through the superconducting transition and those measured during heating with the same magnetic field applied at low temperature, for the heavy-fermion superconductor UPd_2Al_3 . Any hysteresis of this kind finds its phenomenological explanation within the critical state model and is of the same nature as the magnetization hysteresis in $M_{FC}(T)$ and in $M_{ZFC}(T)$ measurements, as described by us in detail in Ref. 7.

Magnetostriction and anisotropy of twin-free single-crystals

$\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$

Jinghua Wang, Guangheng Wu, Xuegen Zhao, Kechang Jia, and Wenshan Zhan
State Key Laboratory for Magnetism, Institute of Physics, CAS, P.O. Box 603, Beijing 100080,
People's Republic of China

A study of the effects of substituting a small amount of Mn for Fe in the Terfenol-D system is presented. The twin-free and $\langle 111 \rangle$ -oriented single-crystal rods of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ were prepared by Czochralski method. The magnetization, lattice constant, Curie temperature, and magnetostriction were examined. From the experimental results, it is possible to determine the effect of Mn substitution on magnetic anisotropy and magnetostriction. Because of Mn substituting for Fe, magnetic moment values of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ show two inflections and the easy magnetization directions also show changes from 1.5 to 300 K at an applied field of 1000 Oe. It strongly suggests that Mn substitution remarkably influences magnetocrystalline anisotropy of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$. Its saturation magnetostrictions are 1.48×10^{-3} and 1.67×10^{-3} , maximum d_{33} values are 1 and 1.5 under compressive stress of 0 and 12 MPa, respectively. These magnetostrictive properties are clearly better than those measured from the $\langle 112 \rangle$ -oriented twinned samples. This is the first time that the experimental data measured from the single-crystalline samples on the magnetic properties of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ are reported. © 1996 American Institute of Physics. [S0021-8979(96)66308-9]

I. INTRODUCTION

$\text{Tb}_x\text{Dy}_{1-x}\text{Fe}_2$, commercially known as Terfenol-D, possesses the largest magnetostriction from -150 to 350°C . However, the large magnetostriction is often associated with a large magnetocrystalline anisotropy. In 1989, Sahashi *et al.*¹ showed that the substitution of Mn in the polycrystalline $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ appeared to increase the magnetostriction at lower magnetic field strengths (~ 2 kOe). In 1990, Teter *et al.*² established that twinned single crystals of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{1-x}\text{Mn}_x)_2$ along the $[112]$ growth direction showed similar results. This suggests the possibility of obtaining lowered anisotropy and reduced hysteresis materials. Since the materials require low anisotropy and large magnetostriction in application, the lower magnetocrystalline anisotropy of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ may make it become a useful magnetostrictive material. Because the samples investigated in previous works are polycrystalline or twinned, and the magnetostriction and d_{33} of the measured samples must be strongly affected by the random orientations of polycrystalline grains and the pinning by the grain and twin boundaries, it is necessary to investigate the single crystals in detail in order to reveal the intrinsic influences of Mn substituting for Fe to the magnetocrystalline anisotropy of this material.

II. EXPERIMENTS AND DISCUSSION

Starting materials of composition $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$, with $y = 1.80\text{--}1.95$, were prepared from Tb, Dy, Fe of the purity of 99.95%, and Mn of the purity of 99.9%. $[111]$ -oriented single-crystal bars approximately $2 \times 2 \times 10$ mm³ were used as seeds. Crystals were grown by the MCGS-3 CZ instrument.³ The single crystals of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ with the $[111]$ axial orientation were obtained with diameters of 6 mm and a maximum length of 50 mm. Chemical analysis was carried out for assuring that the composition of the single crystals were sto-

ichiometric and Mn had been doped at the expected value. The twin-free single-crystalline quality of the crystals were determined by the characterizations with x-ray Laue method and metallographic observation. The characteristic diffraction peaks of (111) , (222) , and (333) obtained by the x-ray diffraction on the transverse sections of the crystals, as shown in Fig. 1, indicates their high perfection.

The x-ray powder diffraction proved that the sample was pure cubic Laves phase. The lattice constant is calculated by diffraction peak datum of crystal surface (422) because diffraction peak data of all crystal surfaces except the (422) surface change with spontaneous magnetization.^{4,5} Its lattice constant of 7.350 Å is larger than that of $\text{Tb}_{0.5}\text{Dy}_{0.5}\text{Fe}_2$ of 7.325 Å. The σ - T curves of all samples were measured by vibrating sample magnetometer under 300–700 K. Then the Curie temperature of 260°C is calculated, which is smaller than that of $\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2$, 380°C . It is believed that the Curie temperature decreased with the dopant of Mn is due to

FIG. 1. The x-ray diffraction peak of transverse section of single-crystal $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$.

FIG. 2. Magnetic moment M vs applied field H of $\langle 111 \rangle$ and $\langle 100 \rangle$ single-crystal $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ at 1.5 and 293 K.

the dramatic decrease of the dominant exchange interaction between Fe and Fe atoms.

Small single-crystal bars of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ cut in $[111]$ and $[100]$ directions in diameter of 1 mm and length of 5 mm were prepared for the measurements of magnetic moment versus applied magnetic field or temperature. Extracting sample magnetometer was used to measure the magnetization curves at 1.5 and 293 K and the curves of magnetic moment versus temperature. The magnetization curves of both the $[111]$ and the $[100]$ oriented samples at 1.5 and 293 K are shown in Fig. 2. It is very clear that the $\langle 111 \rangle$ direction is not a difficult magnetization direction at 1.5 K, nor is the $\langle 100 \rangle$ direction at 300 K. Therefore, it appears that magnetocrystalline anisotropy energy of the $\langle 111 \rangle$ direction is almost the same as that of the $\langle 100 \rangle$ direction. Saturation magnetic moment value of the two different directions is identical. In addition, the magnetic moments of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ and $\text{Tb}_3\text{Dy}_{0.7}\text{Fe}_2$ from 1.5 to 300 K were measured at applied field of 1 kOe as shown in Fig. 3. It can be seen that the magnetic moment values of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ which are oriented in the $\langle 111 \rangle$ and $\langle 100 \rangle$ directions show two inflections at the temperatures of 40 and 160 K, respectively. Moreover, the spin reorientation temperature (magnetocrystalline anisotropy compensation

FIG. 3. Magnetic moment M vs temperature T of $\langle 111 \rangle$ single-crystal $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ at applied field of 1 kOe.

FIG. 4. Magnetostriction λ vs applied field H curves of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ with applied compressive stress from 0 to 12 MPa.

temperature, T_{comp}) of $\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2$ is 240 K at which magnetocrystalline anisotropy undergoes only one conversion. Its easy magnetization direction converts from the $\langle 100 \rangle$ below the T_{comp} to the $\langle 111 \rangle$ above the T_{comp} . However, the magnetic moment values of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ undergo the two conversions as mentioned above. It indicates that the substitution of Mn for Fe in $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ remarkably affects the spin reorientation of this compound and further might influence the magnetocrystalline anisotropy of the rare-earth sites.

The rods of the $[111]$ -oriented single crystals in the dimension of $4 \times 5 \times 15 \text{ mm}^3$ were prepared for measuring magnetostriction with strain gauges at room temperature. Figure 4 shows the relation of the magnetostriction and the compressive axial prestress along the $[111]$ direction. When compressive prestress increases from 0 to 12 MPa, saturation magnetostrictive coefficient, $\lambda_{[111]}$ (along $\langle 111 \rangle$ direction), increases from 1.48×10^{-3} to 1.67×10^{-3} , saturation field increases from 2.5 to 3.0 kOe, and the bias field needed to obtain the maximum value of $d_{33}(d\lambda/dH)$ also increases from 200 to 1000 Oe. Its magnetostriction coefficients $\lambda_{[111]}$ are far larger than those of the $[112]$ oriented.³ It is due to the fact that direction oriented along $[111]$ is the largest direction of magnetostriction and the easiest magnetization direction, that the twin-free single-crystalline samples eliminate the impediment of twin boundaries which hinder the movement of magnetic domains. Moreover, when compressive stress is applied along $[111]$, most magnetic moments must rotate toward $[112]$. The magnetostriction increases because magnetic moments increase contribution to magnetostriction when these magnetic moments rotate toward the $[111]$ direction from the $[112]$ direction. The increase of the bias field is due to the fact that the applied compressive stress makes domain energy of non-180 domain walls increase. Until the Zeeman energy is sufficient to surmount the anisotropy energy barrier and performs work required against the compressive stress, magnetic moment cannot rotate toward the $[111]$ direction. The larger the applied compressive stress is,

the larger the anisotropy energy is. It indicates that the bias field increases with the compressive stress.

III. SUMMARY

Magnetization, Curie temperature, and room-temperature magnetostriction of $\langle 111 \rangle$ -oriented twin-free single-crystalline samples of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ have been measured. The experimental results are as follows.

(1) It has been observed that Curie temperature decreased the lattice constant increased with Mn substituted for Fe in $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$.

(2) The magnetic moment values of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ show two inflections at 40 and 160 K, respectively. In the temperature range of 1.5–300 K, easy and difficult magnetization direction shows a dramatic difference from those of $\text{Tb}_{0.3}\text{Dy}_{0.7}\text{Fe}_2$. It suggests strongly that Mn atom substituting for iron remarkably influences magneto-crystalline anisotropy of the compound.

(3) Magnetostriction, $d\lambda/dH$, and the bias field increased with the increasing of applied compressive stress from 0 to 12 MPa. This result is far larger than those of [112].³ It strongly suggested that [112] direction and twinned boundary influenced substantially the magnetostriction, d_{33} and the bias field.

It is the first time to report the experiment data of twin-free single crystals of $\text{Tb}_{0.5}\text{Dy}_{0.5}(\text{Fe}_{0.9}\text{Mn}_{0.1})_2$ as mentioned above.

Magnetic properties and magnetostriction of twin-free single-crystal $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$

Jinghua Wang, Guangheng Wu, Xuegen Zhao, Kechang Jia, and Wenshan Zhan
State Key Laboratory for Magnetism, Institute of Physics, CAS, P. O. Box 603, Beijing 100080,
People's Republic of China

Magnetization curves, Curie temperature, and lattice constants of twin-free [111]-oriented single-crystal $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0, 0.1$) were investigated. It was observed that with the substitution of Al for Fe, Curie temperature and magnetocrystalline anisotropy decrease, and lattice constants increase. It is shown from the curves of magnetic moment versus temperature that the anisotropy compensation temperature of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ is 280 K, which is higher than 260 K of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$. Besides, the saturation magnetostriction λ_{111} of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ was measured by using strain gauge method. The result indicates that λ_{111} increases from 1.01×10^{-3} to 1.54×10^{-3} as the compressive stress is increased from 0 to 12 MPa, and that the maximal $D_{33}(d\lambda/dH)$ is about 1.0. It is the first time to present the experimental data of the twin-free [111]-oriented single crystal of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$. © 1996 American Institute of Physics. I. INTRODUCTION

In view of the applications, it is necessary for good magnetostriction materials to have low anisotropy energy and large magnetostriction. Clark *et al.*^{1,2} found out that compound $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ (called Terfenol-D) possesses unusually large magnetostriction and magnetocrystalline anisotropy at room temperature (RT). Since then, many researchers have studied other element substitutions for Fe in $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ to search for better materials. Among them, Zhong and Wang³ found out that polycrystalline $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ (x from 1.0 to 1.5) possess large saturation magnetostriction λ_{\parallel} and low magnetocrystalline anisotropy. For instance, the saturation magnetostriction λ_{\parallel} of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ is 1.2×10^{-3} at 25 kOe, which is larger than that of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$. Prajapati *et al.*⁸ established that the substitution of Al for Fe in the (112) twin single crystals of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ produces a material with potential benefits for use in actuators: low magnetocrystalline anisotropy, and high d_{33} . On one hand, it is expected that the similar results can appear in single-crystal samples, on the other hand, considering that the magnetostriction of samples can be strongly affected by grain orientation and twin boundary, we decided to research on twin-free single crystals of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$.

II. EXPERIMENT

The purity of the raw materials prepared for the growth of the single crystals of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$) was as follows: for Tb and Dy, 99.95%, and for Fe and Al, better than 99.9%. The [111]-oriented single-crystal bars with approximately $2 \times 2 \times 10 \text{ mm}^3$ were used as seeds. The crystals were grown in the MCGS-3 CZ apparatus by using Czochralski method.¹⁴ As the result, the single crystals of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$) with the [111] orientation were very well grown and their size is 6–10 mm in diameter and 50–80 mm in length.

Two resultant samples with different target compositions, $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$), were examined by chemical analyses. The results were given in Table I. The accuracy of the chemical analyses is ± 0.01 for Al and Fe, and ± 0.02 for Tb and Dy. As shown in Table I, the ratio of Tb/Dy was 0.39, which is higher than the corresponding one in the target compositions. It results from the preferential loss of Dy, because the vapor pressure of Dy is higher than that of Tb.

The twin-free single crystallinity of the crystals was determined by x-ray Laue spot photographs and metallographic observation. In addition, the characteristic diffraction peaks of (111), (222), and (333) were obtained solely by the x-ray diffraction experiments on the transverse sections of the crystals. The x-ray powder diffraction results indicate that all samples are in single phase of $\text{MgCu}_2(\text{C15})$ structure and possess high perfection.

In addition, the small single-crystalline bars of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$), cut along [111] and [100] orientation and with the diameter of 1 mm and the length of 5 mm, were prepared for measuring magnetization curves and the curves of magnetic moment versus temperature by means of extracting sample magnetometer. Curie temperature was measured by vibrating sample magnetometer. The rods of the single crystal of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ in the dimensions of $4 \times 5 \times 15 \text{ mm}^3$ and with [111] orientation were prepared for measuring magnetostriction by strain gauge at RT.

TABLE I. Chemical composition, Curie temperature, lattice constant and saturation, magnetostriction of single-crystal $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$).

Sample	Chemical comp.	$T_c(^{\circ}\text{C})$	$a(\text{\AA})$	λ_{111}
$\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$	$\text{Tb}_{0.28}\text{Dy}_{0.72}\text{Fe}_{1.99}$	387	7.329	2.400×10^{-3}
$\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$	$\text{Tb}_{0.28}\text{Dy}_{0.72}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$	267	7.539	1.010×10^{-3}

FIG. 1. Magnetization curves of $\langle 100 \rangle$ orientation rod of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ at 1.5, and 260 K, and $\langle 111 \rangle$ orientation rod at 300 K, respectively.

III. RESULTS AND DISCUSSIONS

A. Lattice constants and Curie temperature

Because the half width of x-ray diffraction peaks of cubic Laves phase is very small at the crystal surface of (422),⁵ and spontaneous magnetization influences all data of diffraction peaks except (422), the lattice constants listed in Table I are calculated by the (422) diffraction peak data.^{6,7} In addition, it is observed in Table I that the Curie temperature decreases with Al doping in $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$. We believe that it results from the fact that average exchange interaction between Fe and Fe atoms decreases with the increase of the Al atoms in $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$.

B. Magnetization process

Magnetization curves of $\langle 100 \rangle$ orientation rod of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ at 1.5 and 260 K, and $\langle 111 \rangle$ orientation rod at 300 K, are shown in Fig. 1, respectively. It appears remarkably that the $\langle 100 \rangle$ direction is easy axis at 1.5 K. However, we cannot see clearly which axis is the easy one from the magnetization curves at 260 and 300 K, because the temperature of 260 or 300 K is already close to the anisotropy compensation temperature of the sample and its absolute value of magnetocrystalline anisotropy is smaller. The saturation magnetization M_s of the $[100]$ oriented rod is 85 and 94 emu/g at 260 and 300 K, respectively. The magnetization curves of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ at 1.5 K are shown in Fig. 2, while for 260 and 300 K, the curves are shown in Fig. 3. As shown in Fig. 3, the saturation magnetization for the $[100]$ rod at 260 K and $[111]$ rod at 300 K is 91 and 79 emu/g, respectively. Obviously, the saturation magnetization of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ is less than that of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ at the same temperature. It is well known that the substitution of Al for Fe does not affect the absolute value of the magnetic moments of rare-earth sublattices. However, Al substitution for Fe may cause a deflection of the magnetic moments of the rare-earth sublattices with respect to the magnetizing direction, therefore, the average magnetic moment of every rare-earth atom decreases with the increase of Al content.

FIG. 2. Magnetic moment M vs applied field H of $\langle 111 \rangle$ and $\langle 100 \rangle$ single-crystal rods of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ at 1.5 K.

Furthermore, it is seen in Fig. 2 that magnetic moment almost does not change below the applied magnetic field of 6.5 kOe due to the pinning of magnetic domains. However, at the applied magnetic field of 6.5 kOe, the magnetic moment values of both the $[100]$ and $[111]$ oriented rods jump up suddenly. By contrast, this kind of jump does not occur for the samples of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ at 1.5 K, as shown in Fig. 2. The jump may result from either the pinning of domains by defects and intrinsic stress, or the occurrence of the macroscopic quantum effect of magnetization. In a word, the above results indicate that the Al substitution for Fe strongly affects the magnetic properties of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$ at low temperature.

In Fig. 4 it is clear that both of the two curves of magnetic moment versus temperature for $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al})_2$ ($x=0.0, 0.1$) have an inflection at the temperature so-called anisotropy compensation temperature (T_{comp}). It indicates that magnetocrystalline anisotropy undergoes a transition when the easy direction of magnetization

FIG. 3. Magnetic moment M vs applied field H of $\langle 111 \rangle$ and $\langle 100 \rangle$ single-crystal $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ at 260 and 300 K.

FIG. 4. Magnetic moment M vs temperature T of $\langle 111 \rangle$ single-crystal rods of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$) at an applied field of 1 kOe.

is transited from $\langle 100 \rangle$ below the T_{comp} to $\langle 111 \rangle$ above the T_{comp} . In addition, it can also be seen in Fig. 4 that the T_{comp} of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ is larger than that of $\text{Tb}_{0.27}\text{Dy}_{0.73}\text{Fe}_2$. Since the intrinsic anisotropy of DyFe_2 is larger than that of TbFe_2 while the Curie temperature of TbFe_2 is higher than that of DyFe_2 , the increase of the T_{comp} for Al substitution is equivalent to the increase of the Dy content, or the decrease of Tb content. Therefore, it is reasonable to assume that the average magnetic moment of Tb atoms is affected more strongly by the Al substitution for Fe in $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ than that of Dy atoms. Similarly, we can also assume that the Al substitution decreases the intrinsic anisotropy of TbFe_2 more strongly than that of DyFe_2 . Therefore, the magnetocrystalline anisotropy of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ is decreased.

C. Magnetostriction

Figure 5 shows the relation of compressive axial stress and magnetostriction of the twin-free single-crystal $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$. When the compressive stress is increased from 0 to 12 MPa, the saturation magnetostrictive coefficient along the $[111]$ direction, λ_s , increases from 1.01×10^{-3} to 1.54×10^{-3} , the saturation field increases from 1.8 to 2.3 kOe, and the maximum $d_{33}=1.0$ appears at the applied compressive stress of 12 MPa and magnetic fields from 1.0 to 2.0 kOe. These values are clearly better than those of $\langle 112 \rangle$ -oriented twin single crystal under the same condition.⁸ We believe that it is due to the fact that the $[111]$ is the direction of the largest magnetostriction and the easiest magnetization, and that in the twin-free single-crystalline samples the impediment of the magnetic domain movement, such as twin boundaries, has been eliminated largely. Moreover, when the compressive stress is applied along $[111]$ direction, most magnetic moments must rotate toward $[112]$ direction. The reason for the increase is that the contribution of magnetic moments to magnetostriction is increased when the magnetic moments rotate toward the $[111]$ from $[112]$

FIG. 5. Magnetostriction λ vs applied field H curves of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{0.9}\text{Al}_{0.1})_2$ with applied compressive stress from 0 to 12 MPa.

direction. On the other hand, the applied compressive stress makes domain energy of non-180 domain wall increased, leading to the increase of the bias field. Until the Zeeman energy is sufficient to surmount the anisotropy energy barrier and performs work required against the compressive stress, magnetic moments cannot rotate towards the $[111]$ direction. In fact, the larger the applied compressive stress is, the larger the anisotropy energy is. In a word, the bias field increases with the increase of the compressive stress.

IV. CONCLUSION

From the experimental results of the magnetic and magnetostrictive measurements on twin-free single-crystals $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ ($x=0.0, 0.1$). We can obtain the following conclusions:

(1) The chemical analyses, the increase of lattice constant and the decrease of Curie temperature all confirm that Fe atoms have been substituted by Al atoms.

(2) With x increasing from 0 to 0.1, the anisotropy compensation temperature of $\text{Tb}_{0.27}\text{Dy}_{0.73}(\text{Fe}_{1-x}\text{Al}_x)_2$ increases slightly, while the magnetocrystalline anisotropy energy and the saturation magnetic moment decrease.

(3) The saturation magnetostriction coefficient λ_{111} in the $[111]$ direction increases from 1.01×10^{-3} to 1.53×10^{-3} and d_{33} ($d\lambda/dH$) also increases when compressive stress increased from 0 to 12 MPa. These results are better than those of $\langle 112 \rangle$ -oriented twin single crystal at the same conditions.

Perfect conductivity approximation: Modification for polyphase systems

K. V. Namjoshi, J. D. Lavers, and P. P. Biringer

Department of Electrical and Computer Engineering, University of Toronto, Toronto, Ontario, Canada

In this paper, we use an analytical model to investigate voltage drop across the conductors of a three-phase parallel wire planar transmission line carrying balanced currents. The expressions derived for the voltage drops are identical to those given by the perfect conductor model except for a term arising due to the propagation of fields inside the conductors. The voltage drops thus calculated yield different values for the two end conductors even when they are symmetrically placed with respect to the central conductor. The calculations show that the imaginary part of the correction term is of more significance than the real part. The results obtained show agreement with the measured values. © 1996 American Institute of Physics. [S0021-8979(96)01408-1]

I. INTRODUCTION

In three-phase planar transmission lines carrying balanced currents, it is evident that the voltage drop values across the outer conductors are different from that across the central conductor as its relative position differs from that of the outer conductors. At a first glance it may appear that the outer conductors should have equal voltage drop values if they are symmetrically placed with respect to the central conductor. A numerical calculation by Cao and Biringer¹ has shown that this is not the case. There is a small but finite difference in the values of these two voltage drops. In two-dimensional problems involving single-phase currents, perfect conductivity approximation is frequently used in which the conductors are assumed to be perfectly conducting. Such a model gives quick and fairly acceptable results especially when the skin depth is small in comparison with the conductor cross sectional dimensions and the separation between the conductors. The conductors are assumed to be perfectly conducting for the calculation of the field variables and other related quantities. The power loss if desired is estimated by the knowledge of the surface magnetic field.² In this paper a calculation of voltage drop in a three phase transmission line is presented. The outer conductors of the line are equidistant from the central conductor. We use a model based on the perfect conductivity approximation and show that the model correctly predicts the small difference between the voltage drop values of the outer conductors provided one takes into account the effect caused by the propagation of fields inside the conductors. The voltage drop values thus calculated agree with the measured values.¹

II. THEORY

A schematic of a three-phase parallel wire transmission line with conductors having a circular cross section is shown in Fig. 1. The conductors are nonmagnetic and carry balanced three-phase currents \tilde{C}_1 , \tilde{C}_2 , and \tilde{C}_3 such that \tilde{C}_1 leads \tilde{C}_2 by 120° . The resulting voltage drop across the conductors is obtained with the help of the vector potential at the surface of the conductors. In order to obtain the vector potential at

any of the conductors, in the analysis below, the field variables are expressed in terms of local polar coordinates with the axis of the conductor as origin (Fig. 2). The other two currents are assumed to be filament currents. In the derivation \sim above a variable indicates the phasor representation. Absence of \sim indicates rms value.

A. Conductivity infinite

In this case the vector potential inside the conductors is zero. Vector potential A_z outside the conductor due to a filament current \tilde{C} at $(d,0)$ is given by³

$$A_z = -\frac{\mu_0 \tilde{C}}{4\pi} \log(d^2 + \rho^2 - 2\rho d \cos \phi) - \frac{\mu_0 \tilde{C}}{2\pi} \log \rho + \frac{\mu_0 \tilde{C}}{4\pi} \log(a^4/d^2 + \rho^2 - 2a^2 \rho \cos \phi/d). \quad (1)$$

Therefore, the vector potential at the surface of conductor 2 A_{z2} due to currents \tilde{C}_1 , \tilde{C}_2 , and \tilde{C}_3 is obtained as

$$A_{z2} = -\frac{\tilde{C}_2 \mu_0}{2\pi} \log a - \frac{\tilde{C}_1 \mu_0}{2\pi} \log R - \frac{\tilde{C}_3 \mu_0}{2\pi} \log R \quad (2)$$

or

$$A_{z2} = -\frac{\tilde{C}_2 \mu_0}{2\pi} \log a/R \quad (3)$$

FIG. 1. A schematic of a three-phase transmission line with conductors having circular cross section. R is the distance between the conductors and a is the radius. \tilde{C}_1 , \tilde{C}_2 , and \tilde{C}_3 are the conductor currents.

FIG. 2. The local coordinate system for any conductor showing current \tilde{C} at $(d,0)$. The axis of the conductor under consideration is at the origin.

because $\tilde{C}_1 + \tilde{C}_2 + \tilde{C}_3 = 0$. Voltage drop per unit length, \tilde{E}_{D2} for conductor 2 is obtained by

$$\tilde{E}_{D2} - j\omega \left[-\frac{\tilde{C}_2 \mu_0}{2\pi} \log a/R \right] = 0 \quad (4)$$

or

$$\tilde{E}_{D2} = -\frac{j\omega \tilde{C}_2 \mu_0}{2\pi} \log a/R. \quad (5)$$

Similarly voltage drop across conductor 1, \tilde{E}_{D1} and that across conductor 3, \tilde{E}_{D3} are given by

$$\tilde{E}_{D1} = -\frac{j\omega \tilde{C}_1 \mu_0}{2\pi} \log a/R - \frac{j\omega \tilde{C}_3 \mu_0}{2\pi} \log 2 \quad (6)$$

or

$$\tilde{E}_{D1} = -\frac{j\omega \tilde{C}_1 \mu_0}{2\pi} \left[\log a/R - \frac{1}{2} \log 2 + j \frac{\sqrt{3}}{2} \log 2 \right] \quad (6a)$$

and

$$\tilde{E}_{D3} = -\frac{j\omega \tilde{C}_3 \mu_0}{2\pi} \log a/R - \frac{j\omega \tilde{C}_1 \mu_0}{2\pi} \log 2 \quad (7)$$

or

$$\tilde{E}_{D3} = -\frac{j\omega \tilde{C}_3 \mu_0}{2\pi} \left[\log a/R - \frac{1}{2} \log 2 - j \frac{\sqrt{3}}{2} \log 2 \right]. \quad (7a)$$

B. Conductivity finite

The conductors are solid. The vector potential is obtained by solving the field equations inside and outside the conductor and matching the fields at the interface. Vector potential due to a filament current \tilde{C} at $(d,0)$ now given by Ref. 4. Outside the conductor at $\rho=a$,

$$A_z = -\frac{\tilde{C} \mu_0}{2\pi \log R} + \frac{\tilde{C} \mu_0}{\pi k a} \sum_{n=1}^{\infty} (a/d)^n \frac{I_n(ka)}{I_{n-1}(ka)} \cos n\phi. \quad (8)$$

Inside the conductor at $\rho=a$,

$$A_z = \frac{\tilde{C} \mu_0}{\pi k a} \sum_{n=1}^{\infty} (a/d)^n \frac{I_n(ka)}{I_{n-1}(ka)} \cos n\phi, \quad (9)$$

$$k = \sqrt{j\omega \sigma \mu_0} = (1+j)/\delta.$$

Here, δ is the skin depth, $\omega=2\pi f$ the frequency, σ the conductivity, and μ_0 is the permeability of the free space. I_n is

the modified Bessel function of the first kind and order n . Using Eqs. (8) and (9), the vector potential across the conductor 2, A_{z2} , is written as, inside the conductor at $\rho=a$,

$$A_{z2} = -\frac{\tilde{C}_2 \mu_0}{2\pi k a} \frac{I_0(ka)}{I_1(ka)} + \frac{\tilde{C}_1 \mu_0}{\pi k a} \sum_{n=1}^{\infty} \left(\frac{a}{R} \right)^n \frac{I_n(ka)}{I_{n-1}(ka)} \cos n(\phi + \pi) + \frac{\tilde{C}_3 \mu_0}{\pi k a} \sum_{n=1}^{\infty} \left(\frac{a}{R} \right)^n \frac{I_n(ka)}{I_{n-1}(ka)} \cos n\phi. \quad (10)$$

The first term on the right-hand side of Eq. (10) is due to the known current distribution.⁵

Outside the conductor at $r=a$,

$$A_{z2} = -\frac{\tilde{C}_2 \mu_0}{2\pi} \log a - \frac{\tilde{C}_1 \mu_0}{2\pi} \log R - \frac{\tilde{C}_3 \mu_0}{2\pi} \log R + \frac{\tilde{C}_1 \mu_0}{\pi k a} \sum_{n=1}^{\infty} \left(\frac{a}{R} \right)^n \frac{I_n(ka)}{I_{n-1}(ka)} \cos n(\phi + \pi) + \frac{\tilde{C}_3 \mu_0}{\pi k a} \sum_{n=1}^{\infty} \left(\frac{a}{R} \right)^n \frac{I_n(ka)}{I_{n-1}(ka)} \cos n\phi. \quad (11)$$

The potential drop \tilde{E}_D across the conductor is given by

$$-j\omega A_z = \tilde{E}_D - j\omega A_z \text{ inside outside}$$

Therefore one gets for \tilde{E}_{D2} :

$$\tilde{E}_{D2} = -\frac{j\omega \mu_0}{2\pi} \left[\tilde{C}_2 \log a + \tilde{C}_1 \log R + \tilde{C}_3 \log R - \tilde{C}_2 \frac{I_0(ka)}{ka I_1(ka)} \right],$$

which after simplification leads to

$$\tilde{E}_{D2} = -\frac{j\omega \mu_0 \tilde{C}_2}{2\pi} (\log a/R - T_s), \quad (12)$$

$$T_s = \frac{I_0(ka)}{ka I_1(ka)}, \quad (13)$$

$$T_s = \frac{(1-j)\delta}{2a} \text{ at small } \delta/a. \quad (13a)$$

Equation (12) is similar to Eq. (5) except for a correction term, T_s . It is due to the contribution of the internal vector potential. The correction term depends only on the current distribution in the isolated conductor. Equation (13a) is obtained by using large argument approximation for Bessel functions.⁶ Using a similar procedure, it can be shown that

$$\tilde{E}_{D1} = -\frac{j\omega \mu_0 \tilde{C}_1}{2\pi} (\log a/R - T_s) - \frac{j\omega \mu_0 \tilde{C}_3}{2\pi} \log 2 \quad (14)$$

or for small δ/a ,

TABLE I. Voltage drops across the conductors. $a=1.1$ cm, $R=30$ cm, $f=400$ Hz, $\sigma=5.8 \times 10^7$ S/m, and current=1 kA.

E_D V/m	Phase angle of current	(12)–(15)		
		(5)–(7)	Attn. neglected	Attn. included
E_{D1}	120	1.861	1.877	1.949
E_{D2}	0	1.662	1.666	1.738
E_{D3}	–120	1.861	1.848	1.922

$$\tilde{E}_{D1} = -\frac{j\omega\tilde{C}_1\mu_0}{2\pi} \left(\log a/R - \frac{1}{2} \log 2 - \frac{\delta}{2a} + j \frac{\sqrt{3}}{2} \log 2 + j \frac{\delta}{2a} \right) \quad (14a)$$

and

$$\tilde{E}_{D3} = -\frac{j\omega\mu_0\tilde{C}_3}{2\pi} (\log a/R - T_s) - \frac{j\omega\mu_0\tilde{C}_1}{2\pi} \log 2 \quad (15)$$

or for small δ/a ,

$$\tilde{E}_{D3} = -\frac{j\omega\tilde{C}_3\mu_0}{2\pi} \left(\log a/R - \frac{1}{2} \log 2 - \frac{\delta}{2a} - j \frac{\sqrt{3}}{2} \log 2 + j \frac{\delta}{2a} \right). \quad (15a)$$

It should be remembered that \tilde{E}_{D1} , \tilde{E}_{D2} , and \tilde{E}_{D3} are voltage drops per unit length of the conductors.

III. DISCUSSION

In Eqs. (6) and (7), \tilde{C}_1 lags \tilde{C}_3 by 120° . It can be easily seen that E_{D1} and E_{D3} calculated using Eqs. (6) and (7) have equal magnitudes and they differ from that of E_{D2} . On the other hand, the magnitudes of E_{D1} and E_{D3} as given by Eqs. (14) and (15) are different because of the imaginary part of the correction term T_s in Eq. (13). Various values calculated using the expression derived above are given in Table I. Also given in the table are values which include only the imaginary or the quadrature component T_s . The real part or the attenuation part is not included. These also predict different values for E_{D1} and E_{D3} .

TABLE II. Voltage drops across the conductors. $a=1.1$ cm, $b=1.0$ cm, $R=30$ cm, $f=400$ Hz, $\sigma=5.8 \times 10^7$ S/m, and current=1 kA.

E_D V/m	Phase angle of current	(12)–(15)		
		Attn. neglected	Attn. included	Meas.
E_{D1}	120	1.901	1.921	1.936
E_{D2}	0	1.673	1.694	1.718
E_{D3}	–120	1.839	1.861	1.860

If the conductors are hollow instead of being solid, in Eqs. (12), (14), and (15), the correction term is modified to

$$T_s = \frac{1}{ka} \frac{I_0(ka)K_1(kb) + K_0(ka)I_1(kb)}{I_1(ka)K_1(kb) - K_1(ka)I_1(kb)}. \quad (16)$$

Here, a is the outer radius and b is the inner radius of the conductors. K_n is the modified Bessel function of the second and order n . Values obtained using Eq. (16) for T_s are given in Table II. Also shown in the table are measured values reported by Cao and Biringier.¹ The calculated values are in agreement with the measurement.

IV. CONCLUSIONS

The results presented in this paper indicate that the perfect conductivity model can still be used for three-phase or polyphase circuits provided a suitable correction term is included in the calculation. In the calculation above, the imaginary part of the correction term has a more significant effect than the real part.

Dual-complementary variational methods in eddy currents (abstract)

P. Lois, D. Baldomir, and J. Rivas

Departamento de Física Aplicada, Facultad de Física, University of Santiago de Compostela, Spain

Dual-complementary variational principles and their expressions in static electric and stationary magnetic fields fit quite well into computational methods.^{1,2} We have got a very efficient computer graphics package exploiting these methods. But the main advantage with respect to other methods such as finite elements is that they are associated with the intuitive picture of lines of force for the fields. This enables the designer to use his physical intuition to lead him to practical improvements in the achievement need much less memory and CPU of a computer for most of the usual practical works. Actually our computer package was made on a cheap desk-top computer. Unfortunately these variational methods fail in eddy-current systems. The main reason is that eddy-current equations are equivalent to a diffusion equation which is not a self-adjoint differential operator. Nevertheless we have got to remove this difficulty³ by changing the geometry associated to the conductor. Besides, to employ the exterior algebra of differential forms we get the best understanding of the basics of the mathematical problem. Finally, the paper gives a brief description of the new software that we introduce into this applied mathematical methods. © 1996 American Institute of Physics.

Solution of induction heating problems involving media with hysteresis

A. A. Adly

Electric Power and Machines Department, Cairo University, Giza, Egypt

Induction heating is widely used in various industrial processes. In this paper, the Crank–Nicolson finite-difference approach is employed in the analysis of induction heating problems involving relatively long rods that exhibit hysteresis. The analysis is, thus, reduced to solving a 2D space-time electromagnetic field problem and exact B - H characteristics of rods are taken into account by utilizing Preisach-type models of hysteresis. A detailed numerical example is given in the paper and some sample simulation results covering different excitation frequencies and amplitudes are reported. © 1996 American Institute of Physics. [S0021-8979(96)01508-8]

I. INTRODUCTION

Induction heating is widely used in various industrial processes such as those involving melting, alloying and hardening of metals (see, for instance, Ref. 1). In order to be able to predict and control the outcome of such processes, computations for estimating local field and flux density distributions as well as eddy current and hysteresis core may have to be performed. Such computations become complicated for media having nonlinear B - H characteristics and even more complicated for media exhibiting hysteresis.

In the past, several rigorous analytical formulations for problems dealing with nonlinear saturable magnetic media subject to time varying excitation have been developed (see, for instance, Refs. 2–5). By only considering reversible components of media B - H loops, these formulations may be used to simulate induction heating processes of media exhibiting hysteresis under high excitation currents and/or frequencies. This is because under such conditions hysteresis loss may be ignored in comparison to eddy current loss. Some attempts to account for the hysteresis phenomenon in similar problems have been also made (for example, refer to Refs. 3, 6, and 7). In most of these attempts the complex permeability principle was employed.^{3,6} Though this approach leads to more accurate core loss calculations, it may not yield accurate local predictions. Other reported attempts to account for actual B - H characteristics have resulted in analytical and numerical formulations⁷ that are too complicated to be easily utilized.

The purpose of this paper is to present a numerical approach for solving induction heating problems that involve media exhibiting hysteresis. In the paper, the Crank–Nicolson⁸ finite-difference technique is used to analyze relatively long cylindrical rods with surface excitation along the azimuthal direction and exact B - H characteristics are taken into account by utilizing Preisach-type models of hysteresis.⁹ Hence, the analysis is reduced to solving a 2D space-time electromagnetic field problem in which, for every row of nodes corresponding to the same rod radius, a separate Preisach model is used to keep track of its particular field variation history. No temperature rise effects, though, on media magnetic properties are considered in the presented analysis. Sample simulation results, covering different excitation frequencies and excitation amplitudes, for a specific example are given in the paper.

II. THE ANALYSIS APPROACH

The diffusion equation for the case of an infinitely long rod subject to time varying surface excitation along the azimuthal direction and having uniform conductivity σ can be given by

$$\frac{\partial^2 H_z(r,t)}{\partial r^2} + \frac{1}{r} \frac{\partial H_z(r,t)}{\partial r} = \sigma \frac{dB_z(r,t)}{dH_z(r,t)} \frac{\partial H_z(r,t)}{\partial t}, \quad r \leq R, \quad (1)$$

where R is the rod radius while $H_z(r,t)$ and $B_z(r,t)$ are the axial field and flux density values corresponding to the radius r and time instant t , respectively. Defining h and p in a finite-difference scheme as the distance between adjacent nodes in space and the duration between successive considered instants, in order, r , R , and t may then be expressed by

$$r = (i-1)h, \quad i = 1, 2, \dots, M-1, \\ R = (M-1)h, \quad \text{and } t = (k-1)p, \quad k = 1, 2, 3, \dots \quad (2)$$

Explicit and implicit finite-difference equations representing Eq. (1) can be derived using Taylor expansions about the nodes (i,k) and $(i,k+1)$, respectively. By alternately applying these explicit and implicit equations to successive time rows after shrinking the time step duration to half its value, the following Crank–Nicolson formulation of Eq. (1) can be obtained:

$$iH_{i+1,k+1} + \{1 - 2i - (i-1)/a_{i,k+1/2}\}H_{i,k+1} \\ + (i-1)H_{i-1,k+1} \\ = iH_{i+1,k} + \{1 - 2i - (i-1)/a_{i,k+1/2}\}H_{i,k} \\ + (i-1)H_{i-1,k}, \quad (3)$$

where $H_{u,v}$ is the discrete field value at the mesh coordinates (u,v) and $B_{u,v}$ is the corresponding flux density. The values $H_{M,v}$ may be directly calculated from the surface excitation $J_s(v)$ and the term $a_{u,v}$ may be given by

$$a_{u,v} = p/[\sigma h^2 (dB(H_{u,v})/dH_{u,v})]. \quad (4)$$

In Eq. (3), the predictor-corrector procedure is used for evaluating the appropriate value of the variable a . This means that, first, a half-time step Crank–Nicolson equation is computed using the values of $a_{i,k}$ in order to evaluate $H_{i,k+1/2}$ values. Then, values of $a_{i,k+1/2}$ are computed and, finally, substituted in Eq. (3) to give the field variations between time steps k and $(k+1)$.

FIG. 1. Assumed B - H characteristics of the rod medium.

It should be pointed out that although the Crank-Nicolson formulation is stable for all values of h and p , it has a truncation error of the order $(p^2 + h^2)$ (refer to Ref. 8). This fact, as well as the anticipated skin depth, should be used as a guide while choosing a suitable grid discretization scheme for the finite-difference mesh of a particular problem.

Since media exhibiting hysteresis are the main focus of this study, it should be expected that the term (dB/dH) in Eq. (4) may widely vary for the same H value depending on previous history. For this reason, Preisach models of hysteresis⁹ are utilized in the accurate evaluation of (dB/dH) and, consequently, of the variable a . This can be achieved using the expressions

$$B(H_{u,v}) = -B_{\text{sat}} + \sum_{j=1}^{m-1} (B_{H_j, h_j} - B_{H_j, h_{j-1}}) + (B_{H_m, H_{u,v}} - B_{H_m, h_{m-1}}), \quad (5)$$

$$B(H_{u,v}) = -B_{\text{sat}} + \sum_{j=1}^{m-1} (B_{H_j, h_j} - B_{H_j, h_{j-1}}) + (B_{H_u, v, H_m} - B_{H_u, v, h_{m-1}}), \quad (6)$$

and

$$(dB/dH) \approx \{[B(H + \Delta H) - B(H - \Delta H)]/[2\Delta H]\}. \quad (7)$$

In Eqs. (5) and (6) B_{sat} is the positive saturation flux density value, $B_{\alpha, \beta}$ is the flux density traced along an experimentally measured first-order-reversal curve corresponding to field value β and initiated from the main ascending branch of the hysteresis loop at the field α , while m , H_j , and h_j represent the number of field extrema, the j th local field maximum and the j th local field minimum stored by the model, respectively (see Ref. 9). Expression (5) applies to mesh locations experiencing a decrease in field values while Eq. (6) applies to those experiencing a field increase.

Knowing local field and flux density values corresponding to each time step k , and by the aid of Eq. (2), eddy currents $J_{i,k}$ as well as hysteresis losses P_h and eddy current losses P_e for a rod of unit length can be computed from

$$J_{i-1/2,k} \approx -\left(\frac{H_{i,k} - H_{i-1,k}}{h}\right), \quad i=2,3,\dots,M, \quad (8)$$

FIG. 2. Some local H waveforms for 10^5 A/m, 500 Hz surface excitation.

$$P_h \approx \sum_{i=2,3,\dots,M} \pi h^2 f \{ (i-1)^2 - (i-2)^2 \} \left[\sum_{v=k-N+1}^k (H_{i,v} + H_{i-1,v})(B_{i,v} + B_{i-1,v} - B_{i,v-1} - B_{i-1,v-1})/4 \right], \quad (9)$$

where f is the frequency and N is the number of time intervals p per cycle and

$$P_e \approx \sum_{i=2,3,\dots,M} \pi (2i-3) f \left[\sum_{v=k-N+1}^k p (J_{i,v} + J_{i-1,v})^2 / (4\sigma) \right]. \quad (10)$$

III. A NUMERICAL EXAMPLE AND CONCLUSIONS

The proposed approach has been implemented and its digital computer code has been developed. Numerous simulations have been performed on a sample problem dealing with a silicon steel rod whose conductivity and radius are $2 \times 10^6 \Omega \text{ m}$ and 0.6 cm, respectively. Only steady-state results are reported in this study. The set of first-order reversals shown in Fig. 1 was taken as the experimentally measured B - H characteristics of the rod material. For simplicity, these curves were assumed to be frequency independent.

Field computations were carried out using Eqs. (2)–(7) for various relatively high excitation frequencies and amplitudes, which are typical for induction heating processes. In order to obtain more accurate local field and power loss calculations, appropriate time and space discretizations were chosen to accommodate different frequencies and anticipated skin depths.

In Fig. 2 computed field waveforms at different radii under 500 Hz, 10^5 A/m surface excitation are shown. Two

FIG. 3. Some local H waveforms for 10^4 A/m, 500 Hz surface excitation.

FIG. 4. Some local H waveforms for 10^5 A/m, 5000 Hz surface excitation.

main results can be observed from these waveforms. First, the high excitation level drives the medium into saturation resulting in a low effective permeability and, consequently, a large skin depth δ (i.e., $\delta > R$). Second, the hysteresis phenomenon, which is accurately taken into account in the proposed analysis, has led to the phase differences between H waveforms corresponding to different rod radii. Those two observations are in total qualitative agreement with similar previously reported studies.⁷

Other waveform profiles for 500 Hz, 10^4 A/m and 5000 Hz, 10^5 A/m surface excitations, respectively, are shown in Figs. 3 and 4. By comparing Figs. 2 and 3 it can be deduced that for the same supply frequency the effective permeability varies with applied field level. This is typical for nonlinear magnetic materials and leads to a different skin depth δ ($\delta \approx 0.3 R$ in this case). Figure 4, on the other hand, supports the expected result that for the same applied excitation level of Fig. 2, an increase in its frequency will lead to a decrease in skin depth ($\delta \approx 0.13 R$). However, unlike for linear media, computed skin depths are no longer inversely proportional to the square root of excitation frequencies. Hysteresis and eddy current losses per unit length of the rod have been computed using Eqs. (8)–(10). Some results of these computations are shown in Fig. 5.

It can thus be concluded that, by incorporating Preisach models into the Crank–Nicolson finite-difference formulation, simulation of induction heating processes may be performed while accurately accounting for magnetic properties.

FIG. 5. Sample computed hysteresis (P_h) and eddy current (P_e) losses/unit length.

Simulation results indicate that in such conditions the variation of local fields, hysteresis losses, and eddy current losses with respect to excitation amplitudes and frequencies may significantly deviate from linear media cases. This fact further highlights the importance of using the proposed technique. Even though effects of temperature rise resulting from heat dissipated in the magnetic material has not been taken into consideration, the proposed analysis can be integrated with thermodynamic models to account for this process. In this case, B will have to be calculated for any temperature using first-order reversals measured at the same temperature. Frequency effects on hysteresis loops may also be accounted for by utilizing dynamic Preisach models⁹ or by the aid of other related studies (see, for example, Ref. 10).

Solution of magnetic field and eddy current problem induced by rotating magnetic poles (abstract)

Z. J. Liu and T. S. Low

Magnetics Technology Centre, National University of Singapore, 10 Kent Ridge Crescent, Singapore 0511

The magnetic field and eddy current problems induced by rotating permanent magnet poles occur in electromagnetic dampers, magnetic couplings, and many other devices. Whereas numerical techniques, for example, finite element methods can be exploited to study various features of these problems, such as heat generation and drag torque development, etc.,¹ the analytical solution is always of interest to the designers since it helps them to gain the insight into the interdependence of the parameters involved and provides an efficient tool for designing. Some of the previous work^{2,3} showed that the solution of the eddy current problem due to the linearly moving magnet poles can give satisfactory approximation for the eddy current problem due to rotating fields. However, in many practical cases, especially when the number of magnet poles is small, there is significant effect of flux focusing due to the geometry. The above approximation can therefore lead to marked errors in the theoretical predictions of the device performance. Bernot *et al.*⁴ recently described an analytical solution in a polar coordinate system where the radial field is excited by a time-varying source. A discussion of an analytical solution of the magnetic field and eddy current problems induced by moving magnet poles in radial field machines will be given in this article. The theoretical predictions obtained from this method is compared with the results obtained from finite element calculations. The validity of the method is also checked by the comparison of the theoretical predictions and the measurements from a test machine. It is shown that the introduced solution leads to a significant improvement in the air gap field prediction as compared with the results obtained from the analytical solution that models the eddy current problems induced by linearly moving magnet poles. © 1996 American Institute of Physics. Nonlinear flux diffusion and ac susceptibility of superconductors: Exact numerical results

Z. Koziol^{a)} and R. A. Dunlap

Department of Physics, Dalhousie University, Halifax, N.S., Canada B3H 3J5

The ac response of a slab of material with electrodynamic characteristics $E \sim j^{\kappa+1}$, $\kappa \geq 0$, is studied numerically. From the solutions of the nonlinear diffusion equation, the fundamental and higher-order components of the harmonic susceptibility are obtained. A large portion of the data for every κ can be scaled by a single parameter, $\xi = t^{1/(\kappa+2)} \cdot H_0^{\kappa/(\kappa+2)} / D$, where t is the period of the ac field at the surface, H_0 is its amplitude, and D is the slab thickness. This is, however, only an approximate scaling property: The field penetration into a nonlinear medium is a more complex phenomenon than in the linear case. In particular, the susceptibility values are not uniquely defined by a set of only two parameters, such as κ and ξ , while one parameter, i.e., $t^{1/2}/D$, is sufficient to describe the electrodynamic response of a linear medium. © 1996 American Institute of Physics. [S0021-8979(96)00408-X]

I. INTRODUCTION

The problem of nonlinear diffusion has recently attracted considerable attention in diverse fields of science. One example, which is considered in the present work, deals with the magnetization process of superconductors. In the case when the response of a superconductor to an applied ac field, $H = H_0 \exp(i\omega t)$, is linear, the electrodynamic properties in the superconducting state can be described in terms of the complex conductivity, $\sigma = \sigma_r + i\sigma_i$. In the flux-flow regime of high- T_c superconductors, which occurs in a broad H - T range, it is usually justified to neglect the imaginary component of the complex conductivity. In that case, Maxwell's equations, $\nabla \times \mathbf{B} = 4\pi/c \cdot \mathbf{j}$ and $c\nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t$, provide the following result for the field penetration into a material filling half-space, $x > 0$: $B = H_0 \eta(x) \exp(i\omega t)$, with $\eta(x) = \exp(-\lambda x)$ and $\lambda^2 = 2i/\delta^2$, where $\delta^2 = c^2/(2\pi\omega\sigma_r)$. For a thin plate of thickness $2D$, with the ac field parallel to the large surface of the plate, the following equations hold:¹

$$4\pi\chi' = -1 + \frac{1}{a} \frac{\sinh(a) + \sin(a)}{\cosh(a) + \cos(a)},$$

$$4\pi\chi'' = \frac{1}{a} \frac{\sin(a) - \sinh(a)}{\cosh(a) + \cos(a)}, \quad (1)$$

where $a = 2D/\delta$. A maximum in χ'' results when $\delta(\sigma_r, \omega)$ is comparable to the sample size. Experimental results rarely show susceptibility curves which correspond to the flux-flow result of ohmic-like behavior. Rather, the effects are most often nonlinear. The dependence of the measured susceptibility curves on the excitation current and higher-order components in the harmonic susceptibilities are observed. In the limiting case of very strongly nonlinear response, the critical-state model may be used for the calculation of the ac susceptibility. Then, only one parameter is needed to construct the hysteresis curve for the magnetization, the field of the first full penetration to the sample center, H^* . It is assumed that the harmonic susceptibility components, χ'_m and χ''_m , are defined as Fourier components of the time-

dependent magnetic hysteresis curve, $M(t)/D = \sum_m \chi'_m \cos(m\omega t) + \chi''_m \sin(m\omega t)$, where m is an integer. When, for instance, $H_0 < H^*$, $4\pi\chi'_1 = -(1 - H_0/2H^*)$ is obtained, then $4\pi\chi'_m = 0$ for every odd $m > 1$, and $4\pi\chi''_m = 2H_0/3\pi m H^*$ for all odd $m > 0$. To deal with situations which are more relevant to the description of real experimental results, it is necessary to investigate a nonlinear theory of the magnetic response which would bridge the two limiting cases observed: the linear response and the critical-state one. A fruitful approach to this problem is based on studies of the electrodynamic response of a medium characterized by a power-law current-voltage dependence, $j = \sigma(E)E = \sigma_0 E_0 (E/E_0)^{1/(\kappa+1)}$, where $\kappa \geq 0$. Using Maxwell's equations, the nonlinear diffusion equation describing the penetration of fields into a slab of thickness $2D$ lying in the yz plane¹⁻⁴ can be derived as

$$\frac{\partial \beta}{\partial \bar{t}} = \frac{\partial}{\partial \bar{x}} \left(\frac{\partial \beta}{\partial \bar{x}} \left| \frac{\partial \beta}{\partial \bar{x}} \right|^\kappa \right), \quad \bar{t} = \frac{t}{\tau_0}, \quad \bar{x} = \frac{x}{x_0}, \quad (2)$$

where $\beta = B/E_0$, $x_0 = c/(4\pi\sigma_0)$, and $\tau_0 = 1/(4\pi\sigma_0)$. Recently, studies of solutions of Eq. (2) have been carried out by many authors. The exact analytical description of the response of a superconductor to an abrupt change of external field^{1,2} has been compared with the results of nonlogarithmic magnetization relaxation measurements on high- T_c materials.⁵ Various aspects of the ac response of superconductors has been studied as well by Dorogovtsev⁶ and van der Beek *et al.*⁷ A vector generalization of the critical state model has been proposed by Mayergoyz.^{8,9} Recent results of Gilchrist and Dombre¹⁰ can be compared with numerical results described in the present work. The distinctive feature of solutions of Eq. (2) is that the flux-profile penetration resembles that in the models of the critical state. When a field change is applied, the profile of perturbation spreads out from the surface towards the sample center but a region exists where the field distribution is unchanged inside. If the response to a field change of H_0 is considered, the time after the front of the field change arrives to the center t^* is given by

^{a)}Electronic mail: zkoziol@is.dal.ca; <http://is.dal.ca/~zkoziol/zkoziol.html>

$$\frac{t^*}{\tau_0} = \frac{\kappa}{2(\kappa+1)} \frac{1}{(\kappa+2)} \left[\frac{\Gamma(1/\kappa+1)\Gamma(3/2)}{\Gamma(1/\kappa+3/2)} \right]^\kappa \left[\frac{\beta_0}{H_0} \right]^\kappa \left(\frac{D}{x_0} \right)^{\kappa+2}. \quad (3)$$

The initial magnetization, at $t < t^*$, is given by

$$4\pi M = -H_0 \left(1 - \left(\frac{t}{t^*} \right)^{1/(\kappa+2)} \frac{\Gamma(1/\kappa+3/2)}{\Gamma(1/\kappa+2)\Gamma(1/2)} \right). \quad (4)$$

Equations (3) and (4) imply that a single parameter, $\xi \equiv t^{1/(\kappa+2)} H_0^{\kappa/(\kappa+2)} / D$, can parametrize the short-time magnetization relaxation. It is informative to determine the extent to which this scaling relation is valid with respect to the ac susceptibility (with the replacement of t and H_0 by the ac field period and the field amplitude, respectively).

II. NUMERICAL MODELING OF NONLINEAR DIFFUSION

Most of the calculations of the nonlinear diffusion process presented here have been performed on an array of dimension 50×200 , containing magnetic induction values B at 50 time intervals and 200 space intervals.¹¹ The magnetic field at the surfaces of the sample, $H_0 \sin(\omega t)$, determines the boundary conditions. An average magnetic field $\langle B(t) \rangle$ in the sample has been computed from the magnetic field distribution, every 50 time steps. Next, a Fourier time analysis of $\langle B(t) \rangle$ has been performed and the coefficients of the fundamental and higher-order terms of the harmonic content have been found. The method of computation and its results have been carefully tested. First, the magnetization relaxation process after an abrupt change of the external field has been simulated and numerical results were compared with the known exact analytical expressions derived by Koziol and de Châtel.² Then, the validity of the modeling of the ac response in the limit of linear diffusion on the ac susceptibility, as given by Eq. (1), was checked. It was confirmed also that the ac susceptibility converges towards the critical-state results for large κ . The time range for which the response to the ac field becomes periodic (the initial response at short time does not satisfies this condition) was also investigated. In most cases it is safe to analyze the data taken after the initial 50 000 steps in time evolution (this time depends on κ and H_0). An additional, more reliable, criterion of stable periodicity is based on the criterion that the dc or second harmonic components are not found. At large values of H_0 , the calculations become unstable abruptly. It is possible to overcome this difficulty but at significant expense in computation time (the computation of one susceptibility point requires an average of about 3 h on an IBM-PC computer 486DX2-33 MHz). Therefore, we have concentrated on performing calculations for a larger number of points at lower fields.

III. RESULTS AND DISCUSSION

The penetration of an alternating field resembles, in some ways, the response to an abrupt change of external field; the amplitude of field changes diminishes gradually in the material and, if the field amplitude at the surface is not too large, there is no penetration to a volume separated by a

FIG. 1. The χ'' vs χ' plots of the ac susceptibility for different values of the nonlinearity parameter κ and different periods of the ac field t , (κ, t): (0.667, 25 000, \circ), (0.667, 5000, \triangle), (2, 12 500, \bullet), (2, 5000, \square), (3, 10 000, \diamond), (12, 6250, \blacksquare). Solid lines represent the critical-state and the linear-response limits for a thin plate. The difference between the data for $\kappa=2$ obtained for two different frequencies of the ac field should be noted. The direction of decreasing penetration depth is shown by the arrow.

certain distance from the sample surface. Whether the front of the flux profile in ac penetration propagates towards the center or not, is not an easy question to answer, since the initial very slow propagation which is observed might only be due to unstable initial conditions. Within the accuracy of calculations, the flux profile has a self-replicating shape of diminishing amplitude, with perfect periodicity in time at every point in space but with a phase shift which changes with the distance from the surface. This observation is consistent with the exact results found by Mayergoyz⁸ for penetration of circularly polarized electromagnetic fields. The profiles obtained for one value of an ac field amplitude coincide with the profiles computed for another ac field amplitude, if the phase lag and spatial coordinates are shifted properly.

Plots of χ'' vs χ' shown in Figs. 1 and 2 for different values of the nonlinearity parameter κ converge to the limit of linear diffusion for $\kappa \rightarrow 0$ and to the limit given by the critical-state model for large $\kappa \gg 1$. An important feature of the present results is seen in Fig. 1; susceptibility points computed for different frequencies of the ac field but the same value of κ , do not fall on the same curve. This is different from what it might be expected and seems to have been unnoticed in previous work.¹⁰ In Fig. 3, we show that a simple scaling of the susceptibility with the amplitude of the ac field holds for the data obtained in the range of incomplete flux penetration, $\chi \sim H_0^{\kappa/(\kappa+2)}$. In Fig. 4, the real component of the first-harmonic susceptibility is drawn as a function of $H_0^{\kappa/(\kappa+2)} t^{1/(\kappa+2)} / D$, for different values of the field amplitude H_0 , period of the field and for a few sample sizes. This latter scaling method is not perfect; small differences in the slopes of the data computed for various frequencies is found. This effect may be explained by the fact that flux profiles have a shape which depends on the time of field penetration.

FIG. 2. The third-harmonic susceptibility χ_3'' vs χ_3' compared to the critical-state result represented by the solid line, for the following nonlinearity parameter κ and periods of the ac field t , (κ, t) : (0.667, 25 000, \bullet), (0.667, 5000, \blacklozenge), (1, 5000, \square), and (2, 12 500, \circ). The direction of increasing amplitude of H_0 is shown by the arrow.

One should expect that the parameter $\xi = t^{1/(\kappa+2)} H_0^{\kappa/(\kappa+2)} / D$ will become an exact scaling variable only for the cases when all the parameters, t , H_0 , and D , are simultaneously scaled by a constant λ in the following way: $D \rightarrow \lambda D$, $H_0 \rightarrow (\lambda H_0)^{\kappa/(\kappa+2)}$, and $t \rightarrow (\lambda t)^{1/(\kappa+2)}$.

IV. CONCLUSIONS

When the ac magnetic field does not penetrate to the sample center, the magnetic susceptibility is well described by a simple scaling relation: $\chi \sim \xi$, with

FIG. 3. The real component of the third-harmonic susceptibility as a function of the amplitude of the ac field, computed for an ac field of period equal to 25 000. The slope of solid lines decreases for increasing values of κ , which are the following: 0.667, 0.8, 1.2, 1.333, 1.667, 1.8, 2.333, 2.7, 3.35, 3.7. Similar scaling property is observed for the imaginary component of the third-harmonic susceptibility and for higher-order components as well.

FIG. 4. Scaling of the flux penetration $(4\pi\chi_3' + 1)$ by a function $H_0^{\kappa/(\kappa+2)} t^{1/(\kappa+2)} / D$, where H_0 gives the field amplitude, t gives the period, and D gives the sample thickness. Each of the solid lines passes through the data corresponding to the following values of the nonlinearity parameter κ : 0.667, 1, 2, 3, and 5, for lines with the smallest to largest slope. D is equal to 20 or 100 (there is no distinction between the symbols of the data corresponding to different values of D), while t is 2500 (\circ), 5000 (\square), 6250 (\diamond), 10 000 (\triangle), 12 500 (∇), 25 000 (\bullet), and 100 000 (\blacksquare).

$\xi = t^{1/(\kappa+2)} H_0^{\kappa/(\kappa+2)} / D$. For κ values close to 0, the overall dependence of $\chi''(\chi')$ closely resembles the dependence observed in the linear case. The conductivity, however, computed from $\chi''(\chi')$ data by using the assumption that the linear theory holds, will lead to false information and yield strongly overestimated values. An experimental criterion for detecting nonlinearity would be the observation of the amplitude dependence or the existence of higher order harmonics in the ac response. The susceptibility values of a nonlinear medium are not uniquely defined by a set of two parameters only, such as κ and ξ . For experimental purposes, however, treating ξ as a scaling variable offers a sufficiently accurate method of testing for nonlinear properties of materials.

New method of evaluating the explicit magnetic-state-dependent energy of iron in semiempirical calculations

Genrich L. Krasko

Army Research Laboratory, Materials Directorate, AMSRL-MA-CC, Aberdeen Proving Ground, Maryland 21005-5069

The existing semiempirical methods for use in atomic computer simulations in iron (such as various modifications of the embedded atom method) have not explicitly taken account of the ferromagnetism *per se*. Rather, the adjustable parameters have simply been fitted to mechanical and thermal properties of bcc iron as a ferromagnetic phase. However, when the magnetic properties are essential in affecting localized atomic behavior (e.g., in the vicinity of crystal defects), these methods may be inadequate. To remedy the situation, a procedure is suggested for explicitly calculating the magnetic contribution to the energy of individual atoms, as a function of their atomic environment. The method uses the Stoner approach, as previously developed, and a data base obtained by the *ab initio* calculations on bcc Fe under hydrostatic and tetragonal deformations, and the (111) Fe free surface. The procedure may be incorporated in any semiempirical method: the ferromagnetic contributions to the bulk moduli, C_{11} , C_{12} , and C_{44} are easily calculated and may be used subsequently in adjusting the semiempirical method parameters. Preliminary testing shows a good agreement with the magnetic properties obtained by our *ab initio* calculations. [S0021-8979(96)04408-7]

I. INTRODUCTION

During the recent decade, iron has been the object of extensive study by various theoretical methods. Previous empirical and semiempirical approaches used in atomic computer simulations in iron have not explicitly allowed for magnetism *per se*. Rather, the ferromagnetic effects were taken into account indirectly, by fitting the model parameters to experimental data on bcc iron as a ferromagnetic phase. Obviously, such an approach will be inadequate for cases where the magnetic properties significantly change in the vicinity of crystal lattice defects. Numerous *ab initio* calculations do demonstrate significant changes in local magnetic moments both at point and two-dimensional defects (including grain boundaries and free surfaces). A possible way out is to attempt calculations of the magnetic contributions to the total energy separately, subsequently adding these contributions to the regular empirical potentials allowing for non-magnetic contributions.

In this paper we suggest the procedure of explicitly calculating the ferromagnetic contribution to the energy of individual atoms (as well as the individual atoms' magnetic moments), as a function of their atomic environment. This procedure is based on the Stoner theory of itinerant ferromagnetism,¹ and uses the results of earlier *ab initio* calculations on iron.²⁻⁵

The plan of this paper is as follows. In Sec. II we briefly outline the Stoner model of itinerant ferromagnetism. In Sec. III we discuss the parametrization of the ingredient quantities to be used in semiempirical calculations. Section IV summarizes the procedure and discusses potential applications of the new method in empirical and semiempirical approaches.

II. THE STONER MODEL OF ITINERANT FERROMAGNETISM

The Stoner theory, first suggested in 1939,¹ has been successfully used in recent years in estimating both the equi-

librium magnetization and magnetic energy of band electrons. This was made possible as a result of a rigorous formulation of the Stoner model as a perturbation approach in terms of microscopic electronic theory.⁶⁻¹⁰ Particularly, the fundamental parameter of the theory, the Stoner exchange parameter I was understood in terms of density-functional characteristics.^{8,9} In iron, the theory explained the metamagnetic behavior of the fcc phase.^{1,6}

The Stoner approach in combination with self-consistent non-spin-polarized calculations enables one to perform the detailed analysis of ferromagnetic (FM) behavior, as well as identify all the possible magnetic stationary phases (both stable, metastable, and even unstable), and find the areas of their emergence. This analysis, using traditional spin-polarized calculations, is at present either too cumbersome or even practically impossible.

The Stoner model postulates that the change in energy upon forming a FM state with moment \mathbf{m} consists of two parts. For a given \mathbf{m} , the magnetic contribution to the total energy is³

$$E_m = 1/2 \int_0^{\mathbf{m}} \mathbf{m}' / N(\mathbf{m}') d\mathbf{m}' - 1/4 I \mathbf{m}^2. \quad (1)$$

The first term is the increase in the electron kinetic energy as a result of forming two subbands for spin up and down by flipping $\mathbf{m}/2$ spin down electrons from just below the NM Fermi level into the unoccupied spin-up states just above the Fermi level. The second term is the exchange energy contribution, $-1/4 I \mathbf{m}^2$, where the exchange parameter I is a constant.

The procedure of "constructing" $N(\mathbf{m})$ is described in Ref. 10. The Stoner parameter I can be found from the perturbation theory analysis,⁹ in terms of the NM system as a part of an *ab initio* calculation.

As follows from theory,^{1,8,10} the criterion for appearing a stable (or a metastable) ferromagnetic state is

$$IN(\mathbf{m}) = 1. \quad (2)$$

An important property of the function $N(\mathbf{m})$ is that, being multiplied by the d -electron band width W , it becomes virtually independent of volume, or the Wigner-Seitz (WS) radius s . Then Eq. (2) reads

$$N(\mathbf{m}) = W(s)/I(s), \quad (3)$$

where $N(\mathbf{m}) = WN(\mathbf{m})$. The right-hand side of this equation does depend on s , and this dependence is important.

The Stoner parameter I has a very weak dependence on the volume and the crystal structure of the metal. On the other hand, both the magnetic energy, Eq. (1), the equilibrium magnetic moment \mathbf{m} [as found from Eqs. (2) or (3)], and the equilibrium atomic volume, are rather sensitive to the values of I . In papers²⁻⁴ the value of I , has been adjusted (by factor 1.075) so that the equilibrium WS radius s_0 , for the FM bcc phase be equal to the experimental value.

In those papers *ab initio* (LMTO) calculations were performed for the body centered tetragonal (BCT) Fe for 12 c/a values: $1.0 \leq c/a \leq \sqrt{2}$. For each c/a , self-consistent non-spin-polarized calculations were performed for nine values of the WS radius s ($2.521 \text{ a.u.} \leq s \leq 2.788 \text{ a.u.}$). In each calculation, after convergence had been achieved, the "*ab initio*" Stoner parameters,⁹ $I_0(c/a, s)$, and then $I = 1.075I_0$ were found, and the function $N(\mathbf{m})$ was generated. Then the Stoner equation, Eq. (3), was solved for the equilibrium magnetic moment \mathbf{m} and the magnetic energy E_m , Eq. (1), calculated. The data base generated in this series of calculations will be used in our new method.

The above data, however, reflect only the hydrostatic and tetragonal deformation. An important ingredient of the new method, which is to be used in modeling grain boundaries and free surfaces, should be the information on free surfaces. The necessary data were provided by Dr. Ruqian Wu of CSU, at Northridge, CA.⁵ In the next section we will describe in detail the parametrization of the data and discuss the algorithm of the method.

III. PARAMETRIZATION OF THE FIRST-PRINCIPLES DATA

Any semiempirical method has to be able to somehow describe the environment of the atom of interest. It is known from a vast experience of tight-binding calculations (see, e.g., Ref. 11), that the number of neighbors is an important parameter which plays a crucial role in band-structure calculations. We have chosen, therefore, to introduce the so-called "effective number of neighbors," Z_{eff} , to allow for the atomic environment. Since all the quantities are to be parametrized in terms of Z_{eff} , its definition is not very critical. It is important, however, that Z_{eff} should reflect the real atomic environment. We define

$$Z_{\text{eff}} = \sum (R_{\text{min}}/R)^5 \exp[1 - (R/R_{\text{min}})^2], \quad (4)$$

where the summation is over atom coordinates R (R_{min} is the distance from a given atom to its nearest neighbor). No cut-off radius is introduced, but, in fact, the exponential in Eq. (4) provides a rather fast sum convergence. Figure 1 shows

FIG. 1. $Z_{\text{eff}}(c/a)$ for BCT lattices.

the dependence of Z_{eff} on c/a in BCT lattices. One can see that Z_{eff} for bcc and fcc equal respectively to 10.37 and 12.63, while the corresponding nearest neighbor numbers are 8 and 12. The 10.37 number actually reflects the fact that the six second nearest neighbors in the bcc lattice are also situated rather close to the first nearest neighbors ($R_{2\text{nd}}/R_{1\text{st}} = 1.155$); in the fcc lattice they are farther away ($R_{2\text{nd}}/R_{1\text{st}} = 1.414$). Therefore the six second nearest neighbors in the fcc lattice are less important giving a smaller contribution to Z_{eff} .

Apart from the "environment" or "structure" parameter Z_{eff} , an important parameter is the volume per atom. In a perfect lattice the atomic volume, or, equivalently, the WS sphere of radius s , can be easily found. In a deformed crystal, or a crystal with defects, the atomic volume is difficult to define, and, in fact it is a "bad" parameter.

As was mentioned above, the left-hand side of Eq. (3), $N(\mathbf{m})$, is virtually independent of volume. However, the right-hand side does depend on the local volume, where this dependence is mostly due to the d -electron band width, W .

It is known (see, e.g., Ref. 11), that in perfect crystals $W \sim 1/s^5$. Therefore, it is convenient to parametrize W in the form:

$$W = A(Z_{\text{eff}}) \left(\sum 1/R^{10} \right)^{1/2}. \quad (5)$$

As a result, W has the right volume dependence.

FIG. 2. Factor $A(Z_{\text{eff}})$.

FIG. 3. The Stoner parameter, $I(Z_{\text{eff}})$ (approximated by two polynomials).

The values of W are easily found as a byproduct of *ab initio* calculations: our data base comprises the values of W for a number of BCT lattices, as well as the bcc (111) free surface.⁵ Figure 2 shows the results of fitting the function, Eq. (5) to the *ab initio* d -band widths W . The function $A(Z_{\text{eff}})$ is approximated by a polynomial in the interval $5.2 \leq Z_{\text{eff}} \leq 12.61$ [note the Z_{eff} values between 5.2 and 10.354 correspond to atoms in the vicinity of the (111) free surface].

We assume that the Stoner parameter I is only weakly volume dependent. However, it does depend on atomic environment, i.e., on Z_{eff} . We approximated the values of I (as found from the *ab initio* calculations, and augmented by factor 1.075) by two polynomials in Z_{eff} (Fig. 3).

Thus, if $N(\mathbf{m})$ is known, then, for a given Z_{eff} and W , Eq. (3) can be solved for the magnetic moment, $\mathbf{m} = \mathbf{m}(W/I)$. The next step is calculating E_{kin} , the kinetic energy contribution [the integral in Eq. (1); Fig. 4 shows E_{kin} vs \mathbf{m} for three lattices], and then the total ferromagnetic energy, E_m .

Both the $N(\mathbf{m})$, $\mathbf{m}(x)$, $x = W/I$, and $E_{\text{kin}}(\mathbf{m})$, calculated separately, can be directly introduced into the computer code as DATA statements. The three data sets are two-dimensional arrays, x and Z_{eff} being the variables.

It is known, that ferromagnetism is unstable beyond a definite range of atomic volume/structure values. This translates into a definite restriction for the values of $x = W/I$.

FIG. 4. The E_{kin}/W vs \mathbf{m} for bcc, BCT with $c/a=1.24$, and fcc.

These are also found from *ab initio* calculations and approximated by a polynomial in x .

IV. CONCLUSION

Following the above procedure, the computer code has been developed in the form of subroutine

STONER (**ni**, **ri**, **amag**, **emag**).

The calculation procedure is as follows. The subroutine STONER is called from a main program which generates **ni** and **ri**, the total number of neighboring atoms and their distances from the atom of interest (**ni** should include as many atoms as it may be necessary for the Z_{eff} to converge). The subroutine returns **amag** and **emag**, the magnetic moment on the atom of interest and its ferromagnetic energy. Wherever Eq. (3) does not have a ferromagnetic solution (the ferromagnetic solution is unstable), or E_m is positive (the ferromagnetic solution is metastable), the subroutine returns the values $\mathbf{m}=0$, and $E_m=0$.

The test runs of the subroutine for BCT lattices for $s=2.661$ (equilibrium volume for bcc Fe) from $c/a=1.0$ (bcc) through $c/a=1.32$ (at higher c/a 's at this volume the ferromagnetic state is unstable) showed an excellent agreement between the values of \mathbf{m} and E_m calculated by the new method and the results of our LMTO calculations.

The new procedure can be easily adopted by any semi-empirical method. The most popular method, the embedded atom method, in its various modifications, fits some of the calculated quantities to their experimental values. In all EAM versions, among those quantities are the bulk modulus and the three elastic moduli: C_{11} , C_{12} , and C_{44} .

In order to implement the new procedure, a series of calculations for hydrostatic, tetragonal, and trigonal deformations of bcc Fe have to be performed, and the ferromagnetic contributions to the corresponding elastic moduli found. Then, this information is to be used in fitting the adjustable parameters in the corresponding EAM, provided that the magnetic contributions are calculated by the new method.

ACKNOWLEDGMENTS

The author is grateful to Dr. Ruqian Wu for providing his unpublished results of the electronic densities of states for the (111) free surface in Fe. Valuable discussions with Dr. R. J. Harrison are also acknowledged. The LMTO code used in our *ab initio* calculations was developed by Professor N. Christensen.

Three-dimensional modeling techniques applied to regions with small susceptibility variations (abstract)

R. J. Hill-Cottingham and J. F. Eastham
University of Bath, Claverton Down, Bath BA2 7AY, United Kingdom

I. R. Young and J. V. Hajnal
GEC/Hirst Research Centre, Elstree Way, Borehamwood, Herts WD7 1RX, United Kingdom

The article considers the modeling of regions where the susceptibility is 0.01–10 ppm different from the majority of the space of interest. These calculations are of use in MR imaging, for example, in one possible application, the susceptibility of an haemorrhagic deposit could be adduced. Two methods are considered. Firstly, the use of finite element modeling using double precision arithmetic in conjunction with carefully set convergence limits. Secondly, a method which considers the induced polarity in the region of enhanced susceptibility, and calculates the difference field. The work is validated initially by calculating analytically the field perturbation produced by a sphere of susceptibility of 1×10^{-8} and comparing the results with the two methods given above. It is shown that excellent agreement is obtained. As a further confirmation the field produced by a short cylindrical object was measured experimentally using a MR scanner and again the applicability of both modeling techniques was confirmed. © 1996 American Institute of Physics.

An efficient three-dimensional demagnetizing field calculation scheme (abstract)

A. S. Kazmi and R. C. Giles
Department of Electrical, Computer, and Systems Engineering, Boston University, Boston, Massachusetts 02215

We present an efficient three-dimensional demagnetizing field calculation scheme for micromagnetic simulations of the domain walls in garnet-like materials. We take advantage of the fact that the domain wall is nearly planar and distribute computational power nonuniformly between the bulk of the material and the wall regions. We use fast Fourier convolutions along one dimension (approximately parallel to the domain wall) and a two-dimensional variant of Greengard's adaptive fast multipole method in the other dimensions.¹ Even a 2D nonadaptive multipole method has the time complexity of the order of N , for N points in contrast to full Fourier convolution ($N \log N$) or direct methods (N^2). The adaptive method is based on maintaining a point-to-point error bound which allows us to work at high resolution in the region of the domain wall and coarser resolution in the bulk material. In this case, the calculation scales proportional to the domain wall size rather than the sample volume. The error bound calculation is important for our method and it depends on the Gegenbauer's addition theorem for the modified Bessel functions.² Due to the complex nature of this addition theorem, we have relied on numerical methods, comparing our method to the direct calculations for small size samples. We have implemented this scheme on an SGI workstation and we are reporting the outcome of the 2D adaptive fast multipole method implementation. We have studied the relationship between error bounds, domain wall size, and actual time. We have also compared our results with that of M. Redjda's method.³ © 1996 American Institute of Physics.

Computational calculations of magnetic relaxation and viscosity in small magnetic grains

J. M. Hernández, X. X. Zhang, and J. Tejada

Fac. Física, Universitat de Barcelona, Diagonal 647, Barcelona 08028, Spain

In this article we present a phenomenological model which simulates very well the magnetic relaxation behavior experimentally observed in small magnetic grains and single domain particles. In this model, the occurrence of quantum tunneling of magnetization below a certain temperature is taken into account. Experimental results for different materials are presented to illustrate the most important behavior deduced from our model. © 1996 American Institute of Physics. [S0021-8979(96)79308-5]

The problem of magnetic relaxation is present in many situations of science and technology. In the last years, big efforts have been made with the aim to explain better; (a) the law governing the magnetic relaxation and the effects of energy barrier distributions,¹⁻⁴ (b) the temperature dependence of magnetic viscosity,⁵⁻⁷ (c) the relation switching field distribution and magnetic noise in recording media.⁸

The simplest magnetic system for studying the dynamics of magnetization reversal is a single domain particle with uniaxial anisotropy. In the presence of an applied field opposite to the magnetization of the particle, the frequency of the magnetization reversal, at temperature T , is given by Ref. 9 $\Gamma = \omega \exp(-U/k_B T)$, where ω is the attempt frequency at an order of 1 GHz, and $k_B T$ is the thermal energy. U is the energy barrier height to the magnetization reversal which is in the form of $U = KV[1 - H/H_K]^{1/2}$ where K is the magnetic anisotropy constant, V is the volume of the magnetic switching unit (assumed to be the entire single domain particle) and H is the applied magnetic field. The anisotropy field, H_K , is defined in terms of K and the particle saturation magnetization M_s : $H_K = 2K/M_s$.

We also incorporate to our model the effect of quantum tunneling under-barrier transitions of the magnetization below a certain crossover temperature, T_{CR} ,¹⁰ which separates the classical and quantum regimes. Therefore the expression for the attempt frequency can be written as $\Gamma = \omega \exp[-U/k_B T_{ESC}(T)]$ where the escape temperature,

$T_{ESC}(T)$, presents in magnetic systems, a temperature dependence characteristic of weak damping processes. Here we assume that $T_{ESC}(T) = T_{CR} \coth(T_{CR}/T)$, because this matches, qualitatively well, the behavior observed in both, magnetic systems and Josephson junctions.^{11,12} In zero field, quantum transitions dominate below $T_{CR}(0)$. When an external magnetic field is applied, there is a reduction in the value of T_{CR} which depends on the magnetic field strength, H , and the anisotropy field, H_K (Refs. 10 and 13)

$$T_{CR}(H) = T_{CR}(0)\epsilon^{1/2},$$

$$\text{where } \epsilon = 1 - H/H_K.$$

(1)

As one applies a magnetic field H_1 on such a system consisting of N identical particles, the magnetic moment of the system, at its equilibrium state at temperature T , is $\mu_{eq}(H_1) = NM_s V g(H_1)$ with $g(H) = \tanh(M_s V H / k_B T)$. If the magnetic field is changed to a new value, H_2 , the evolution of the magnetization moment to a new equilibrium state is governed by

$$\mu(t) = NVM_s \{g(H_2) + [g(H_1) - g(H_2)] \exp(-t\Gamma)\}. \quad (2)$$

If a size distribution of the particles $f(V)$ is taken into account in the model, as it does exist in a real physical material, then the magnetization (density of magnetic moment) relaxes as

$$M(t) = \frac{\int_0^\infty f(V) VM_s \{g(H_2) + [g(H_1) - g(H_2)] \exp(-t\Gamma(V))\} dV}{\int_0^\infty V f(V) dV}. \quad (3)$$

In our computation process, it has been assumed that the distribution of volume, $f(V)$, have the form of the so-called log-normal distribution¹⁴ given by $f(V) = (A/V) \exp[-\alpha \log^2(V/V_m)]$ where V_m is the average volume of the particles and α is related with the inverse of the distribution width.

Equation (3) is the basis of our calculations. This integral has been performed using numerical integration in the interval of volumes in which the distribution of sizes takes significant values.

Figure 1(a) shows the variation with time of the remnant magnetization in zero magnetic field at different temperatures, when previously the system has been saturated by an applied field H_1 , much larger than the anisotropy field, H_K , and assuming $T_{CR} = 0$. This M vs t data have been fitted using a time-logarithmic law

$$M(t) = [M(t=0) - M(t \rightarrow \infty)] [B - S(T) \log(t)], \quad (4)$$

where $S(T)$ is the so-called magnetic viscosity, $M(t=0)$ is the initial magnetization and $M(t \rightarrow \infty)$ is the equilibrium

FIG. 1. (a) Relaxation of the magnetization for different temperatures from 0.3 to 11.4 K as a function of time in a logarithmic scale. (b) Temperature dependence of the magnetic viscosity deduced from (a).

magnetization at the second field, that is $M(t \rightarrow \infty)$ is equal to zero at zero applied field H_2 . From Eq. (4), it is noted that the factor $[M(t=0) - M(t \rightarrow \infty)]$ have all the dependence of the relaxation process on the initial and the final equilibrium states. Therefore, the dependence of $S(T)$ on the temperature is perfectly characterizing the relaxation behavior of the particles.

Figure 1(b) shows the dependence of the magnetic viscosity obtained from Fig. 1(a) on temperature. A near perfect linear dependence of S on T is observed at temperatures much lower than the blocking temperature, which corresponds to the case that the relaxing fraction of the total magnetization is very small. The maximum of the viscosity appears at temperature near the theoretical expectation for the blocking temperature, $T_B = KV_m/[k_B \ln(t_{\text{mes}}\omega)]$, (7.14 K in this case) at which the inverse of the jumping frequency, Γ , for the mean volume particles equals the measuring characteristic time, t_{mes} . At temperatures higher than the blocking, the magnetic viscosity decreases because most of the barriers are overcome in a very short time and do not contribute to the slow relaxation processes.

Quantum tunneling processes are considered by introducing a nonzero value for the crossover temperature T_{CR} , below which the switching processes are independent of temperature. First we have computed the case when the transition temperature T_{CR} remains constant and the average volume of the grains (and therefore the average barrier height) is different. This situation corresponds to systems having different values for the ratio between the blocking temperature and the crossover temperature, T_B/T_{CR} . Both, crossover and blocking temperature scale with the anisotropy constant of the material, but while the crossover temperature does not depend on extensive parameters, blocking is proportional to the volume of the magnetic unit. Therefore the modification of the volume of the particles or grains under the assumption of constancy of the crossover temperature, induces only variations in the blocking temperature. It is, large particles may have large values for the ratio T_B/T_{CR} . In Fig. 2 we show different $S(T)$ curves for the situation when the ratio T_B/T_{CR} ranges from 5 to 1, with T_{CR} equals 3.3 K. The most remarkable fact is that the maximum of the viscosity disappears when T_B/T_{CR} is 1. This situation corresponds to the

FIG. 2. Effect of the quantum tunneling in the dependence of the viscosity with the temperature for different values of the ratio between the blocking temperature and the crossover temperature.

case when the system enters directly from the classical superparamagnetic regime onto a quantum superparamagnetic regime without any intermediate blocked state. This should be the ideal case to observe the resonance due to quantum coherence.¹⁵

In Fig. 3 we present the low temperature $S(T)$ values for the case when the applied field, H_2 , modifies the crossover temperature between the classical and quantum regime, see Eq. (1). This corresponds to the case of a unique set of single domain particles or grains relaxing under the action of different values for the applied field. As the field values increase, the plateau in the viscosity appears at lower temperatures and the quantum viscosity values increase as a consequence of the reduction on the barrier heights.

The situation of Fig. 1 is compared with relaxation experiments performed on a CuCo granular material. Transmission electron patterns in similar systems suggest that this granular material has a log-normal size distribution in agreement with our assumption that the particles in the calculation have a log-normal size distribution. The zero field cooled (ZFC) magnetization vs temperature gives a blocking temperature $T_B = 8$ K.¹⁶ The relaxation measurements were per-

FIG. 3. Temperature dependence of the magnetic viscosity for different applied fields. The numbers near each curve indicate the ratio between the applied field and the anisotropy field.

FIG. 4. (a) Magnetic relaxation in a particulate CuCo sample at different temperatures. (b) Dependence of the magnetic viscosity on temperature from (a).

formed from a field $H_1 = 100$ Oe, after which the field was removed, and then the variation of magnetization with time was measured during few hours. Figure 4(a) shows the relaxation of the remnant magnetization measured at different temperatures; a nearly perfect logarithmic time relaxation behavior is observed. The temperature dependence of magnetic viscosity is presented in Fig. 4(b), and has the same behavior as that shown in Fig. 1(b).

In case of the occurrence of quantum tunneling in the relaxation process, we can compare the experimental results obtained on CuDy granular material¹⁷ which has different sizes with the calculated ones presented in Fig. 2. The temperature dependence of magnetic viscosity for samples with composition of Cu(100 Å)Dy(20 Å) and Cu(100 Å)Dy(40 Å) is shown in Fig. 5. The two samples have very similar anisotropy fields H_K and consequently the same value for the crossover temperature T_{CR} . We have also found, from ZFC and FC measurements, that these two systems have blocking temperatures of 2.4 K and 10 K, respectively, which corresponds to the different average size of the grains in the two samples. The theoretical predictions indicate that the transition temperature for these two systems is $T_{CR} = 3$ K. There-

FIG. 5. Magnetic viscosity in two granular structured CuDy thin films: Cu(100 Å)Dy(20 Å) (circles) and Cu(100 Å)Dy(40 Å) (squares).

FIG. 6. Magnetic viscosity vs T for different applied fields in a TbFe random magnet.

fore we are in a situation in which we have two different values for the ratio T_B/T_{CR} , 0.9 and 3, respectively. For the sample with $T_B = 2.4$ K (Cu(100 Å)Dy(20 Å)), we have observed, in agreement with the calculations, that there exists a direct transition from the thermal superparamagnetic behavior to the quantum regime.

In addition, the effect of applied field on the relaxation and quantum tunneling has been found in a TbFe random magnet.¹⁸ The dependence of magnetic viscosity on the temperature obtained in relaxation measurements with different applied fields is shown in Fig. 6. It is clearly seen that the behavior of $S(T, H)$ in Fig. 6 is very similar to that in Fig. 3, although the experimental results obtained on the random magnetic thin film corresponds to a relaxation process due to the turning of magnetic moments in different clusters. However, this similarity is not surprising due to the fact that interactions between clusters do not affect the relaxation inside each cluster as a consequence of the large magnetic anisotropy values in these random magnets.

Loss simulations in magnetostrictive actuators

G. Engdahl

Power Engineering, ABB Corporate Research, S-72178 Västerås, Sweden

A. Bergqvist

Electric Power Engineering, Royal Institute of technology, S-10044 Stockholm, Sweden

Power losses in a magnetostrictive actuator have been studied. The system consists of a cylindrical rod of Terfenol-D, a surrounding magnetic circuit to get a homogeneous flux, a mechanical load applied to the rod ends, and an electric coil. We consider transient operating conditions with time-varying driving voltage. Nonlinearity and hysteresis are handled by using a magnetomechanical hysteresis model as the constitutive law. Eddy currents and field constriction are taken into account by a finite difference representation of the diffusion equation for the active rod. Coil losses are trivially found through Ohm's law. The influence of laminations in the magnetostrictive rod on the eddy current loss is examined using finite element methods. © 1996 American Institute of Physics. [S0021-8979(96)04308-0]

I. INTRODUCTION

The feasibility of utilizing highly magnetostrictive materials in various suggested applications depends strongly on the total efficiency of the electromechanical system. Numerous methods have been proposed regarding the modeling of specific loss processes such as eddy currents, hysteresis, etc., in highly magnetostrictive materials.^{1,2} In this work, efforts have therefore been spent on the assembly of a simulation tool that simultaneously accounts for the main loss processes resistive heating in drive coils, eddy currents and hysteresis. The individual algorithms are described in more detail in Refs. 3–5. A specific actuator is used as an example to demonstrate the capability of the design tool.

II. MAGNETOSTRICTIVE ACTUATOR DEFINITION

The magnetostrictive actuator used as the demonstration object is visualized in Fig. 1 and is of a type described in Ref. 6. It comprises of NdFeB permanent magnets (coercivity 875 kA/m) that are traversed by the main dynamic component of the flux created by the driving coil (100 turns). No losses in the soft magnetic conductors (relative permeability 1000) are considered. This is a reasonable assumption if these parts consist of laminated silicon-iron.

In the demonstration example, the actuator is fed electrically by a voltage source in series with a capacitor tuned for obtaining series resonance. The actuator is mechanically biased by 25.5 MPa and loaded purely resistively by 25 kN/m. The active material is considered either solid or laminated (four separate laminates), where a lower effective conductivity is assumed in the latter case.

III. MODELING PROCEDURES

In earlier works,^{3,4} a two-dimensional model for magnetostrictive drive elements under transient conditions was developed. In the model, the behavior of the active Terfenol-D rod is represented using finite difference approximations for Newton's law of motion and the diffusion equation in axisymmetric coordinates. The interactions with the external electric circuit and mechanical load are described by additional sets of equations. Due to nonlinearity in the

Terfenol-D, calculations are performed using time-stepping techniques rather than Fourier transforms, even under sinusoidal excitation.

An important aspect is the magnetomechanical constitutive law for the Terfenol-D. We have used two different types of material laws. In the first, a single-valued nonlinear relation entirely estimated from experiments is assumed. That is, strain S and flux density B are measured for a large number of values of field H and stress T . B and S can then be evaluated for any argument (H, T) by interpolation. In the second method, a recent hysteresis model⁵ is used which is based on the following notions: Magnetization and strain are expressed as superpositions of contributions from a number of independent particles. The state of each particle is uniquely determined by its own magnetization and strain and its evolution is governed by the principle of entropy maximization. Hysteresis is assumed to be due to a friction-like resistance to any changes in the state which is represented by assuming that the free energy of individual particles has many densely distributed local minima. To characterize a material, the model uses a few parameters determining hysteretic properties in addition to the same anhysteretic database as the first method.

FIG. 1. Magnetic circuit of the considered actuator. All measures in mm.

FIG. 2. Orientation of laminations in magnetostrictive rod.

IV. INITIAL CALCULATIONS

The influence of the external magnetic circuit is represented by using a reluctivity circuit parameter. This is done in order to avoid incorporating a finite element or finite difference representation of the entire magnetic circuit in the transient simulations since this would greatly slow down the computations. It has previously been established that this approach is a good approximation.⁴ The reluctivity value was numerically calculated for the scheme shown under magnetostatic conditions using finite elements and found to be 5.0×10^6 A/V s.

Eddy currents in the active material can be reduced by using laminated magnetostrictive rods as shown in Fig. 2. In such a case, the system is strictly speaking not axisymmetric. However, to account for this, and calculate in three dimensions would be computationally very expensive and as an approximation, such a laminated rod may be treated as a homogeneous rod with reduced conductivity. In order to find the effective conductivity, we considered an infinitely long rod with laminations as shown and constant permeability and solved for the time-harmonic case with constant H -field amplitude along the border as boundary condition using an FE program. The use of laminations has the effect of both increasing the flux amplitude and decreasing the loss angle. It was found that if an effective conductivity in a homogeneous rod is chosen such that the loss angle is the same as for a laminated rod, the flux amplitude is different and vice versa. A useful compromise between fitting the loss angle and the flux amplitude, appears to be the rule

$$\sigma_{\text{eff}} = \sigma / (N + 1)^2, \quad (1)$$

FIG. 3. Relative flux amplitude and sine of loss angle vs number of laminations N in an infinitely long cylindrical rod. Frequency = 1000 Hz, relative permeability = 5, conductivity $\sigma = 1.67 \times 10^6$ Ω m, rod radius $r = 15$ mm. Solid lines show calculations for a laminated rod. Dashed lines show calculations for a homogeneous rod with conductivity $\sigma / (1 + N)^2$.

where σ is the conductivity of Terfenol-D and N is the number of laminates. Figure 3 shows the error in flux magnitude and loss angle when this method is used.

V. RESULTS AND CONCLUSIONS

Simulations have been performed for frequencies $f = 200, 400$, and 1000 Hz. We have compared the situations with and without laminations and with and without hysteresis in the active material, giving a total of twelve cases. The common external condition in all considered cases is that the driving voltage is sinusoidal with amplitude 8 V. We consider the average values over one period of the mechanical power P_{mech} , resistive loss P_{res} , eddy current loss P_{eddy} , and hysteresis loss P_{hyst} . The total power is

$$P_{\text{tot}} = P_{\text{mech}} + P_{\text{res}} + P_{\text{eddy}} + P_{\text{hyst}}. \quad (2)$$

TABLE I. Power parts in various simulation cases.

f (Hz)	η_{mech}	η_{res}	η_{eddy}	η_{hyst}	η_{err}
Laminations, no hysteresis					
200	18.9	73.2	8.0	0	-4.9
400	47.2	38.3	14.5	0	0.2
1000	50.6	11.4	38.1	0	-18.7
No hysteresis, no laminations					
200	5.6	37.2	57.2	0	-3.3
400	13.8	18.4	67.7	0	-7.2
1000	11.0	7.8	81.0	0	-5.9
Hysteresis and laminations					
200	5.7	57.9	5.1	31.3	-17.8
400	30.8	36.4	10.4	22.3	-6.4
1000	30.8	13.0	20.4	35.8	-28.9
Hysteresis, no laminations					
200	3.0	37.4	41.4	24.6	-6.4
400	10.3	25.5	56.0	8.3	2.5
1000	6.7	9.9	72.5	10.9	1.9

Table I shows the relative contributions of these terms defined as $\eta_{\text{mech}} = P_{\text{mech}}/P_{\text{tot}}$, $\eta_{\text{res}} = P_{\text{res}}/P_{\text{tot}}$, etc. Among these, η_{mech} is the efficiency of the device. The last column in the table gives an quantity η_{err} defined as

$$\eta_{\text{err}} = (P_{\text{supp}} - P_{\text{tot}})/P_{\text{supp}}. \quad (3)$$

Here P_{supp} is the average supplied electrical power over one period. Because of energy conservation, we should have $P_{\text{supp}} = P_{\text{tot}}$. The fact that we do not, must therefore be an error which may have several causes. One is that the average mechanical power is a couple of magnitudes smaller than its positive and negative peak values. The estimate of its average value is therefore prone to significant numerical error. A different kind of error source is due to the constitutive law of the active material. In the nonhysteretic case, we should, due to energy conservation, have $\oint (BdH + SdT) = 0$ for any closed cycle and at every point in space. Using Green's formula, this implies the Maxwell relation $\partial B/\partial T = \partial S/\partial H$. However, the material data used in calculations showed some deviation from this relation. This could be due to an experiment error though it is then not clear which variables are incorrectly measured. It might also be due to how the anhysteretic curves are estimated from the hysteretic measured data. The same error is present in the hysteretic calculations, since the hysteresis model also used these data.

The inclusion of hysteresis in the simulations increased the computational time by a factor of 3–5 times. This was partly because each evaluation of B and S at a point in space and time took about five times longer and partly because in some cases a shorter time step was required to get convergence. We attempted the alternative method of estimating the hysteresis loss by performing the simulations without hysteresis and then subsequently using the hysteresis model with the resulting spatial average of the field and stress in the rod

as input. Obviously, this will inevitably lead to an imbalance between input and output power. Furthermore, it turned out that the hysteresis loss computed in this manner greatly deviated from the one calculated with the hysteresis model incorporated in the simulation model, sometimes by a whole magnitude. The simplified method therefore seems dubious although it is not impossible that it could be useful under different conditions.

It is observed that eddy currents are very significant for nonlaminated rods, and that laminations considerably improve the overall efficiency at all frequencies, although this is partially offset by the fact that coil losses increase. With hysteresis, the eddy current loss will decrease which is due to the decrease in flux density amplitude. The efficiency is in all cases overestimated, when hysteresis is neglected, most notably for the case of $f = 200$ Hz and a laminated rod.

A way to get around the imbalance of power could be to force the anhysteretic data to obey the Maxwell relation, overriding the experimentally measured values. For instance, instead of using direct measurements to find S as a function of H and T , it might be preferable to determine it from measured values of H , T , and B as $S = \int (\partial B/\partial T) dH$

Analysis and optimization of synchronous magnetic couplings

E. P. Furlani

Imaging Research and Advanced Development, Eastman Kodak Company, Rochester, New York 14653-5305

Permanent magnet couplings made from rare-earth materials such as NdFeB render substantial torque, and are used in numerous applications that cannot be addressed with conventional materials. Moreover, formulas have been developed for designing and optimizing these devices. In this paper, the design formulas are summarized and demonstrated via optimization of practical coupling geometries. © 1996 American Institute of Physics. [S0021-8979(96)01608-4]

I. INTRODUCTION

Synchronous magnetic couplings are used to transmit torque between two separated members with the most common applications involving the activation of devices in sealed containers. The two most common coupling configurations are radial and axial couplings. Rigorous torque predictions for either configuration require three-dimensional analysis, and while various numerical techniques such as the finite element analysis (FEA) are applicable, they tend to be awkward for the kind of parametric analysis that is often desired. To remedy this, formulas have been developed for predicting the torque of both types of couplings by Furlani *et al.*¹⁻³ These formulas, which are based on three-dimensional analytical analysis, apply to couplings made from materials such as NdFeB with a second quadrant constitutive relation of the form

$$B = \mu_0(H + M_s).$$

It is important to note that the analysis takes into account the magnets only, and does not (rigorously) apply when additional nonlinear materials are present (constituting a mag-

netic circuit). The formulas are expressed as finite sums of elementary functions, and are well suited for parametric analysis and optimization. Moreover, they have been verified using standard numerical methods as well as empirical data.^{4,5} These formulas are summarized below and calculations are performed that demonstrate their effectiveness in the optimization of practical coupling geometries. In addition, the advantage of using sintered versus bonded NdFeB material is discussed.

II. AXIAL COUPLINGS

Axial couplings consist of two axially polarized, multipole disks that are constrained to rotate about a common axis (Fig. 1). One of the magnets is driven by an external source while the other is connected to a load. As the driven magnet rotates it imparts an axial force and torque to the load. The efficiency of the coupling is a function of several variables, including the material properties, number of poles, dimensions, separation distance, and the relative angular offset of the magnets. The force and torque are given by

$$F(\theta) = \frac{\mu_0}{4\pi} N_{\text{pole}} M_s^2 \left\{ \frac{\pi(R_2^2 - R_1^2)}{N_{\text{pole}} N_r N_\theta} \right\}^2 \sum_{m=0}^2 \sum_{n=1}^{N_{\text{pole}}} \sum_{i=1}^{N_r} \sum_{j=1}^{N_\theta} \sum_{i'=1}^{N_r} \sum_{j'=1}^{N_\theta} \frac{(-1)^{(n+m)} \alpha_m h_m}{\{[r_i^2 + r_{i'}^2 - 2r_i r_{i'} \cos(\theta_j - \theta_{j'}(n))] + h_m^2\}^{3/2}}, \quad (1)$$

and

$$T(\theta) = \frac{\mu_0}{4\pi} N_{\text{pole}} M_s^2 \left\{ \frac{\pi(R_2^2 - R_1^2)}{N_{\text{pole}} N_r N_\theta} \right\}^2 \sum_{m=0}^2 \sum_{n=1}^{N_{\text{pole}}} \sum_{i=1}^{N_r} \sum_{j=1}^{N_\theta} \sum_{i'=1}^{N_r} \sum_{j'=1}^{N_\theta} \frac{(-1)^{(n+m)} \alpha_m r_i r_{i'} \sin[\theta_j - \theta_{j'}(n)]}{\{[r_i^2 + r_{i'}^2 - 2r_i r_{i'} \cos(\theta_j - \theta_{j'}(n))] + h_m^2\}^{3/2}}, \quad (2)$$

where θ is the relative angular offset of the two magnets (the torque is zero when $\theta=0$), N_{pole} is the number of poles, N_r and N_θ are "mesh" parameters that characterize the discretization of the "surface charge" on each magnet, and h_m and α_m are given by

$$h_m = h + m t_m \quad (m=0,1,2),$$

$$h = \text{separation of magnets } (m),$$

$$t_m = \text{thickness of magnets } (m),$$

and

$$\alpha_m = \begin{cases} 1 & m=0 \\ 2 & m=1, \\ 1 & m=2 \end{cases}$$

respectively. These and the remaining variables are defined in detail in a previous paper.¹ Note that these formulas entail nested summations of elementary functions and are readily programmed. However, note that when programming multiple summations, a higher degree of accuracy can be achieved with fewer mesh points (i.e., lower values N_r and N_θ) if the total of a single summation over one index is

FIG. 1. Axial coupling.

evaluated and saved separately (as an intermediate step), and then the totals of the successive summations are added together to obtain the final sum.

III. RADIAL COUPLINGS

Radial couplings consist of two coaxial, radially polarized, multipole cylinders that are constrained to rotate about a common axis (Fig. 2). Again, one of the magnets is driven while the other is connected to a load. The torque is given by

$$T(\theta) = \frac{2N_{\text{pole}}M_s^{\text{out}}h\tilde{R}}{N_z^{\text{out}}N_r^{\text{out}}} \sum_{p=0}^{N_z^{\text{out}}} \sum_{q=0}^{N_r^{\text{out}}} S_z(p)S_r(q)r(q) \times B_r^{\text{in}}\left[r(q), \theta + \frac{\pi}{N_{\text{pole}}}, z(p)\right], \quad (3)$$

where M_s^{out} is the magnetization of the outer magnet, $B_r^{\text{in}}(r, \theta, z)$ is the field of the inner magnet, N_z^{out} and N_r^{out} are the discretization parameters for the outer magnet (numerical integration), $h = Z_2^{\text{out}} - Z_1^{\text{out}}$, $\tilde{R} = R_2^{\text{out}} - R_1^{\text{out}}$, and θ is the rela-

FIG. 2. Radial coupling.

FIG. 3. Torque vs number of poles (axial coupling).

tive angular offset of the two magnets. Again, these and the remaining variables are described in previous work.²

IV. ANALYSIS

In this section, the coupling formulas are applied to the optimization of practical coupling geometries. The axial coupling is treated first. Consider an application that requires a torque of $T=1.0$ Nm to be transmitted through a 10 mm enclosure. To begin the analysis, choose the following nominal magnet dimensions:

$$R_1 = 1 \text{ cm (inner radius),}$$

$$R_2 = 4 \text{ cm (outer radius),}$$

$$t_m = 1.5 \text{ cm (height).}$$

The coupling is to be made from cold-pressed NdFeB with a 10% concentration of binder by volume. The author has found that a magnetization value of $M_s = 4.3 \times 10^5$ A/m renders accurate data for this material (the corresponding value for 28 MGOe sintered NdFeB is $M_s = 7.16 \times 10^5$ A/m). The analysis was performed on a Sun SPARCstation 10 with for-

FIG. 4. Torque and force vs θ (axial coupling).

FIG. 5. Torque vs number of poles (radial coupling).

mulas (1) and (2) implemented in Fortran. The peak torque was computed as a function of the number of poles (N_{pole}) for a series of separations $h=10, 12, 14$, and 16 mm (Fig. 3). The analysis shows that the peak torque (which occurs at an angular offset of π/N_{pole}) occurs at 6, 6, 4, and 4 poles, respectively. In addition, the magnets can be separated by as much as 14 mm and still render the desired torque. To complete the analysis, the torque and force were computed as a function of θ for the 14 mm separation (Fig. 4). The maximum force is 60 N, and is attractive (negative) at $\theta=0^\circ$ and repulsive (positive) at 90° . For this analysis the summation parameters N_r and N_θ were set to 12, and it took approximately 10 s to compute each torque value.

For the radial coupling consider an application that requires a torque of $T=90$ Nm to be transmitted through a 0.45 cm enclosure (i.e., the magnets, which are coaxial, must have a 0.45 cm radial gap between them). Assume that the magnets are to be made from cold-pressed NdFeB and have the following dimensions:

$$R_1^{\text{in}}=1 \text{ cm} \quad (\text{inner radius of inner magnet}),$$

$$R_1^{\text{out}}=5 \text{ cm} \quad (\text{inner radius of outer magnet}),$$

$$R_2^{\text{out}}=8 \text{ cm} \quad (\text{outer radius of outer magnet}),$$

$$h=5 \text{ cm} \quad (\text{length}).$$

The peak torque was computed as a function of the number of poles (N_{pole}) for a series of inner magnet, outer radial values $R_2^{\text{in}}=3, 3.5, 4$, and 4.5 cm (when $R_2^{\text{in}}=4.5$ cm there is a 0.5 cm radial gap between the inner and outer magnet). Note that the peak torque (which occurs at an angular offset of π/N_{pole}) occurs at 4, 6, 6, and 10 poles, respectively (Fig. 5). The analysis shows that a 10 pole coupling with $R_2^{\text{in}}=4.5$ cm is optimal for this application. For this analysis formula (3) was implemented in Fortran, and the summation parameters N_r , N_θ , and N_z were set to 10, 10, and 20, respectively.² It took approximately 5 s to compute each torque value. This is in sharp contrast to the hours it would take to perform a similar optimization using FEA.

Lastly, once torque calculations have been performed for a given value of magnetization M_s , the torque for any other value can be quickly determined because it is proportional to M_s^2 . Thus, the torque obtained using 28 MGOe sintered NdFeB is 2.77 times greater than for cold-pressed NdFeB.

V. SUMMARY

Synchronous magnetic couplings can be readily designed and optimized for a given application using analytically based formulas. The analysis can be completed in a few minutes on a modern workstation and can completely eliminate costly and time consuming fabrication and testing.

A randomized microstructure based on the Voronoi diagram is proposed for micromagnetic models. Simulations illustrate variability of extrinsic magnetic properties with microstructure, medium noise dependence on medium properties, and jitter dependence on trackwidth. © 1996 American Institute of Physics. [S0021-8979(96)00508-6]

I. INTRODUCTION

Much research into the structural details of the magnetic patterns which store information in magnetic recording systems has been based on micromagnetic models of magnetic recording media.¹⁻⁴ Most of these models make use of a regular grain structure, tiling the medium plane with a spatially periodic array of hexagons or rectangles. Regular grain structures have a number of advantages, including the property that they form a space-filling partition of the medium plane. However, Miles has demonstrated that such microstructure regularity yields unphysical anisotropic properties,⁵ and has proposed an alternative randomized grain geometry.^{6,7} In the alternative strategy, grains are placed at random in the medium plane with care taken not to allow grain overlap. This strategy generates isotropic microstructures, but a multistage process is necessary to achieve an acceptable packing fraction.

In this paper we present a micromagnetic model with randomized microstructure as a generalization of regular microstructure models. The resulting grain geometry is irregular, and also forms a partition of the medium plane with no gaps between grains. The grain generation algorithm is built on the concept of the Voronoi diagram.⁸

II. IRREGULAR GRAIN GEOMETRY

Let $S \subset \mathbf{R}^2$ be a set of N planar points, $\{P_1, \dots, P_N\}$. The Voronoi diagram of S , $\mathcal{V}(S)$, is the set of regions $\{R_1, \dots, R_N\}$, where

$$R_k = \{x \in \mathbf{R}^2 : \forall l \neq k : \|x - P_k\| \leq \|x - P_l\|\}. \quad (1)$$

The computation of the Voronoi diagram is a well-studied problem in the field of computational geometry and can be performed using software available from The Geometry Center at the University of Minnesota.⁹ When the set of initial points S is a lattice, the Voronoi diagram has a regular structure. Figure 1(a) illustrates the generation of a hexagonal grain structure as the Voronoi diagram of a lattice S . A generalization to irregular structures is achieved by choosing a randomly dispersed set of initial points S . Figure 1(b) illustrates the generation of an irregular grain structure as the Voronoi diagram of a set of points S generated by a Poisson point process.¹⁰

Because the Voronoi diagram is a partition of the medium plane, this method of generating randomized microstructure does not encounter the difficulty of a low packing fraction. In addition, Voronoi regions are an attractive grain

model because they approximate the structure which results from crystal growth outward from nucleation sites represented by the points in S .

Three magnetic interactions are represented. Each grain exhibits uniaxial anisotropy with an easy axis chosen at random. The magnetic interactions are represented by dipole-dipole interactions computed at the centroids of the grains with moments proportional to grain area. This simple representation is accurate for long-range interactions. Short-range magnetostatic interactions are expected to be dominated by exchange interactions. Exchange interactions are computed in such a way as to split the exchange energy of a domain wall equally between each pair of grains which share an edge, following Muller and Indeck.¹¹ Therefore, the exchange interaction between two grains is proportional to the length of the edge they share. Grains are selected in a random sequence. The magnetization of each selected grain is rotated in the medium plane in response to its local field until it reaches a local minimum of magnetic energy. It has been demonstrated that the final magnetization state of this evolution algorithm is nearly sure to be a local minimum of total magnetic energy.¹²

III. SIMULATION RESULTS

To compute hysteresis loops, two $2 \mu\text{m} \times 2 \mu\text{m}$ medium patches were generated, one of hexagonal grains, the other of irregular grains. The grains were generated to have an average area of 2500 nm^2 . Each patch was initialized to a state of negative saturation. Applied field values were stepped from -1.5 to 1.5 times the anisotropy field and back in steps of 0.03 times the anisotropy field, with a complete relaxation to a stable state at each step of the computation. The exact loop computed depends on the particular set of random easy axes selected. For each of the medium patches, Fig. 2 contains a plot of the average of five computed hysteresis loops, where each computed loop is based on a different random selection of easy axes. The values of remanence vary by as much as

FIG. 1. Hexagonal (a) and irregular (b) grain structure.

FIG. 2. Hysteresis loops for hexagonal and irregular grain structures.

3% from the average. Coercivity values vary as much as 11%. Significant differences in the extrinsic magnetic properties, particularly in the coercivity, arise from the different microstructures.

Figure 3 depicts a track of recorded information as represented by the model. The trackwidth is $1\text{ }\mu\text{m}$, and the bit cell length is 150 nm , values sufficient to achieve an areal density of more than 4 Gbits per square inch. The thickness of the medium δ is 30 nm . The initial data pattern was directly set in the simulation; it was not generated by simulation of a recording process. The grey scale of the figure represents the component of magnetization parallel to the recorded track, with white representing magnetization fully saturated toward the left and black representing magnetization fully saturated toward the right.

The magnetic pattern which remains after the interacting grains have relaxed to a stable state depends on the medium properties. Figure 4 is the pattern after relaxation for medium A with properties selected to show very little corruption of

FIG. 3. High-density data pattern.

FIG. 4. Data pattern after relaxation for medium A. M_r , $\delta=1.59\text{ memu/cm}^2$. $H_c=6800\text{ Oe}$.

the recorded pattern. Hysteresis loop computation for medium A yields a coercivity of 6800 Oe and a remanence of 531 emu/cm^3 . Figure 5 is the pattern after relaxation for medium B with somewhat more realistic properties. Hysteresis loop computation for medium B yields a coercivity of 3100 Oe and a remanence of 535 emu/cm^3 . The initial "recording" can easily be recovered visually from the corrupted magnetization of medium B by viewing Fig. 5 at a glancing angle from the bottom. Such a perspective approximates the integration across the trackwidth performed by a read head.

When corrupted magnetic patterns are read, the deviations of the resulting waveform from ideal are called medium noise. The read process was simulated using the Karlqvist model for an inductive read head. Figure 6 illustrates medium noise for an isolated transition recorded on both medium A and medium B, compared with the ideal pulse corresponding to an uncorrupted pattern.

One type of distortion caused by medium noise is the displacement of pulses from their intended locations.¹³ This jitter has been theoretically and experimentally shown to de-

FIG. 5. Data pattern after relaxation for medium B. M_r , $\delta=1.61\text{ memu/cm}^2$. $H_c=3100\text{ Oe}$.

FIG. 6. Medium noise examples.

pend on the trackwidth of the read head.^{14,15} For a trackwidth of W , the root-mean-square value of the jitter σ is predicted by theory to be

$$\sigma = CW^{-1/2}, \quad (2)$$

where C is a constant depending in part on the transverse coherence length and average grain size of the recording medium.

Simulations were performed to reproduce a set of experiments on a precision recording tester.¹⁵ To simulate writing at many locations on a medium, 200 $7.3 \mu\text{m} \times 14 \mu\text{m}$ medium patches were generated with average grain area of $40\,000 \text{ nm}^2$ and a thickness of 50 nm . Model parameters were selected to yield a coercivity of 1250 Oe and a

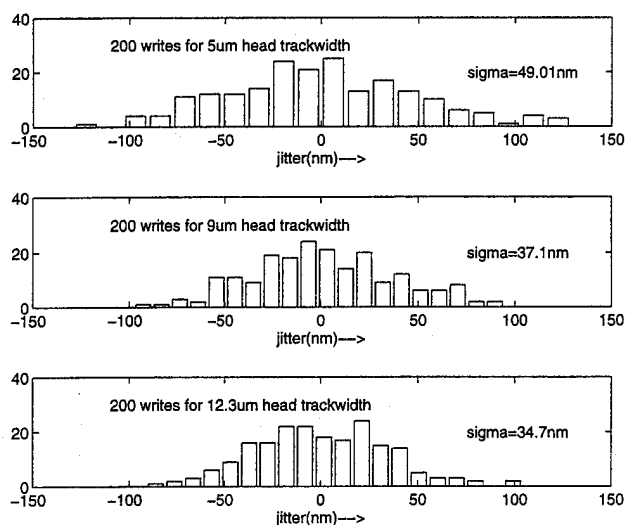

FIG. 7. Jitter histograms.

FIG. 8. Root-mean-square jitter vs trackwidth.

remanence-thickness product of 4 memu/cm^2 , matching the values of the medium in the experiments. The readback pulse waveforms from isolated transitions were computed for each patch for read heads and recorded tracks of width 5 , 9 , and $12.3 \mu\text{m}$. The jitter values from these computed waveforms form the histograms of Fig. 7. As predicted by theory, a larger trackwidth yields a smaller value of root-mean-square jitter. Figure 8 is a log-log plot of σ vs W , with a slope of -0.40 . The simulations were also performed without allowing the interacting grains to relax to a stable state. A corresponding slope of -0.63 was computed. Neither set of simulations closely matches the theoretically predicted value of $-1/2$. However, they are qualitatively consistent with it.

In molecular compounds, the magnetic properties depend on the coupling between the magnetic moments of transition metal ions, rare earth ions, and/or free radicals. This coupling is often antiferromagnetic, but can give a high spin moment in some particular cases. When organic molecules form crystals, again the coupling between molecules can be antiferromagnetic or ferromagnetic like. In a few cases the ferromagnetism, only due to nitroxide radicals, has been observed at low temperature. We present here a more general case of a manganese(II) derivative of an "imidazole substituted nitronyl nitroxide" with complex behavior. The high temperature properties can be explained by ferrimagnetic coupling between the Mn and nitroxide spins. At low temperature a weak intermolecular coupling appears below 10 K, as well as a weak ferromagnetic component below 4.5 K. These low temperature properties might be due to the canting of antiferromagnetically coupled spins. © 1996 American Institute of Physics.

Recently, the wavelet analysis is being applied to the various fields, such as image data compression in informatics and spectrum analysis of the electrocardiogram. In the present article, we propose the two approaches, employing the wavelet analysis for the human heart diagnosis. One is the data base approach, and the other is an inverse approach searching for the magnetic field source of the human heart. The data base approach is an application of the data compression to the magnetocardiogram. Also, the magnetic field source searching is an application of the spectrum analysis to the magnetocardiogram. The results reveal that the data base approach makes it possible to identify the normal or abnormal heart, and the magnetic field source search is capable of estimating the current distribution of a distinct heart. © 1996 American Institute of Physics. [S0021-8979(96)79408-1]

I. INTRODUCTION

Recent investigations concerning the magnetocardiogram (MCG) are establishing their possible use for human heart diagnosis, because the MCG data contain the activation current information of the human heart.¹ In order to utilize the MCG data for heart diagnosis, it may be classified by two approaches; one is a direct reading of the information from the MCG data, and the other is an inverse approach searching for the activation current in the heart. Direct application of the MCG data for diagnosis requires a great deal of experience and skillfulness for reading the information included in the MCG data. On the other hand, the inverse approach does not require intensive experience, but it is essential to exploiting a solution strategy for the inverse source problem.²⁻⁴

Recently, the wavelet analysis has been developed for the image data compression in informatics and for the spectrum analysis of the ECG.^{5,6}

In the present article, we applied the wavelet analysis to the human heart diagnosis. The wavelet analysis is applied to the MCG data compression for the data base oriented diagnosis. This proposes an expert system employing the wavelet analysis. Further, the wavelet analysis is applied to the inverse approach searching for the current distribution in the heart.

As for results, the data base approach makes it possible to identify the normal or abnormal heart. Also, it is shown that the magnetic field source searching approach is capable of estimating the current distribution of the distinct heart.

Thus, we show that our approaches employing the wavelets are quite effective tools for MCG diagnosis.

II. APPLICATION OF THE WAVELET ANALYSIS TO MCG DIAGNOSIS

A. Discrete wavelet transform

In the present article, we employ Daubechie's analyzing wavelets. Let us consider the following linear transformation:

$$\mathbf{X}' = \mathbf{C}\mathbf{X}, \quad (1)$$

where \mathbf{X} is a data vector with order of n ; n must be a power of 2; and \mathbf{C} is

$$\mathbf{C} = \begin{bmatrix} c_0 & c_1 & c_2 & c_3 & 0 & 0 & \cdot & 0 & 0 & 0 & 0 \\ c_3 & -c_2 & c_1 & -c_0 & 0 & 0 & \cdot & 0 & 0 & 0 & 0 \\ 0 & 0 & c_0 & c_1 & c_2 & c_3 & \cdot & 0 & 0 & 0 & 0 \\ 0 & 0 & c_3 & -c_2 & c_1 & -c_0 & \cdot & 0 & 0 & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & 0 & 0 & 0 & \cdot & c_0 & c_1 & c_2 & c_3 \\ 0 & 0 & 0 & 0 & 0 & 0 & \cdot & c_3 & -c_2 & c_1 & -c_0 \\ c_2 & c_3 & 0 & 0 & 0 & 0 & \cdot & 0 & 0 & c_0 & c_1 \\ c_1 & -c_0 & 0 & 0 & 0 & 0 & \cdot & 0 & 0 & c_3 & -c_2 \end{bmatrix}. \quad (2)$$

In Eq. (2), the first, third, fifth, and the other odd rows generate the components of data convolved with the coefficients c_0, c_1, c_2, c_3 . This corresponds to a weighted integral operation. On the other side, the even rows generate the com-

FIG. 1. An example of MCG data compression by means of the wavelet transformation. (a) An original MCG map, (b) a wavelet spectrum of (a), (c) a reproduced MCG map from the 100% spectrum in (b), and (d) the reproduced MCG map from the 6.25% spectrum in (b).

ponents of data convolved with the coefficients $c_3, -c_2, c_1, -c_0$. This corresponds to a weighted differential operation.

In order to carry out an inverse linear transformation, the coefficients c_0, c_1, c_2, c_3 should be determined by

$$C^T C = I, \quad (3)$$

where I is a n th order unit matrix and the superscript T refers to the transpose of matrix C^T in Eq. (3):

$$C^T = \begin{bmatrix} c_0 & c_3 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & c_2 & c_1 \\ c_1 & -c_2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & c_3 & -c_0 \\ c_2 & c_1 & c_0 & c_3 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ c_3 & -c_0 & c_1 & -c_2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & c_2 & c_1 & c_0 & c_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & c_3 & -c_0 & c_1 & -c_2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_2 & c_1 & c_0 & c_3 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & c_3 & -c_0 & c_1 & -c_2 & 0 \end{bmatrix} \quad (4)$$

From Eqs. (2)–(4), we have

$$c_0^2 + c_1^2 + c_2^2 + c_3^2 = 1, \quad c_2 c_0 + c_3 c_1 = 0. \quad (5)$$

Equation (5) is composed of the two equations and has the four unknowns c_0, c_1, c_2, c_3 . To determine the coefficients c_0, c_1, c_2, c_3 , we have to consider the following conditions:

$$c_3 - c_2 + c_1 - c_0 = 0, \quad 0c_3 - 1c_2 + 2c_1 - 3c_0 = 0. \quad (6)$$

From Eqs. (5) and (6), we have

$$c_0 = \frac{1+\sqrt{3}}{4\sqrt{2}}, \quad c_1 = \frac{3+\sqrt{3}}{4\sqrt{2}}, \quad c_2 = \frac{3-\sqrt{3}}{4\sqrt{2}}, \quad c_3 = \frac{1-\sqrt{3}}{4\sqrt{2}}. \quad (7)$$

The set of coefficients c_0, c_1, c_2, c_3 in Eq. (7) is Daubechie's fourth-order analyzing wavelets.

For simplicity, let us consider a data vector \mathbf{X} with the order of 16:

$$\mathbf{X} = [x_1 \ x_2 \ x_3 \ x_4 \ x_5 \ x_6 \ x_7 \ x_8 \ x_9 \ x_{10} \ x_{11} \ x_{12} \ x_{13} \ x_{14} \ x_{15} \ x_{16}]^T. \quad (8)$$

In the case, the linear transformation using the matrix C_{16} yields

$$\mathbf{X}' = C_{16} \mathbf{X} = [s_1 \ d_1 \ s_2 \ d_2 \ s_3 \ d_3 \ s_4 \ d_4 \ s_5 \ d_5 \ s_6 \ d_6 \ s_7 \ d_7 \ s_8 \ d_8]^T. \quad (9)$$

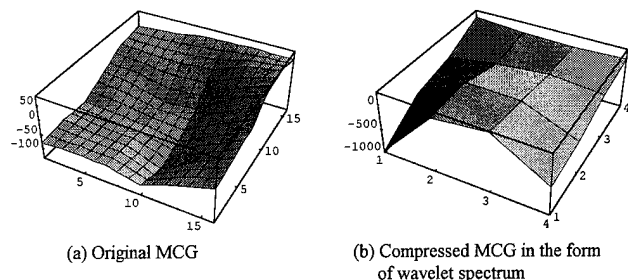

FIG. 2. The data compression of the MCG map of normal heart at QRS 30.0 (ms). (a) An original MCG map, and (b) the compressed MCG map in the form of wavelet spectrum.

The elements in vector \mathbf{X}' are sorted by using the following matrix:

$$P_{16} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad (10)$$

Thus, we have

$$P_{16} \mathbf{X} = P_{16} C_{16} \mathbf{X} = [s_1 \ s_2 \ s_3 \ s_4 \ s_5 \ s_6 \ s_7 \ s_8 \ d_1 \ d_2 \ d_3 \ d_4 \ d_5 \ d_6 \ d_7 \ d_8]^T. \quad (11)$$

Further transformation to the elements $s_1, s_2, s_3, s_4, s_5, s_6, s_7, s_8$ in Eq. (11) yields

$$W^{(2)} \mathbf{X} = [S_1 \ S_2 \ S_3 \ S_4 \ D_1 \ D_2 \ D_3 \ D_4 \ d_1 \ d_2 \ d_3 \ d_4 \ d_5 \ d_6 \ d_7 \ d_8]^T. \quad (12)$$

Similar transformation to s_1, s_2, s_3, s_4 in Eq. (12) yields

$$W^{(3)} \mathbf{X} = [S_1 \ S_2 \ D_1 \ D_2 \ D_1 \ D_2 \ D_3 \ D_4 \ d_1 \ d_2 \ d_3 \ d_4 \ d_5 \ d_6 \ d_7 \ d_8]^T. \quad (13)$$

The transformation matrices used in Eqs. (12) and (13) are

$$W^{(2)} = (P'_{16} C'_{16}) (P_{16} C_{16}), \quad W^{(3)} = (P''_{16} C''_{16}) (P'_{16} C'_{16}) (P_{16} C_{16}), \quad (14)$$

$$P'_{16} = \begin{bmatrix} P_8 & 0 \\ 0 & I_8 \end{bmatrix}, \quad C'_{16} = \begin{bmatrix} C_8 & 0 \\ 0 & I_8 \end{bmatrix}, \quad P''_{16} = \begin{bmatrix} P_4 & 0 \\ 0 & I_{12} \end{bmatrix}, \quad C''_{16} = \begin{bmatrix} C_4 & 0 \\ 0 & I_{12} \end{bmatrix}. \quad (15)$$

Equation (13) is the finally obtained wavelet spectrum. The elements $S_1 S_2$ in (13) are called the Mother Wavelet coefficients, and the others are called the wavelet coefficients at each level.

Inverse wavelet transform is carried out by

$$\begin{aligned} \mathbf{X} &= [W^{(3)}]^T W^{(3)} \mathbf{X}, \\ [W^{(3)}]^T &= [(P''_{16} C''_{16})^T (P'_{16} C'_{16})^T (P_{16} C_{16})^T]^T \\ &= (P_{16} C_{16})^T (P'_{16} C'_{16})^T (P''_{16} C''_{16})^T \\ &= C_{16}^T P_{16}^T (C'_{16})^T (P'_{16})^T (C''_{16})^T (P''_{16})^T. \end{aligned} \quad (16)$$

B. MCG data compression

Figure 1 shows an example of MCG data compression by means of the wavelet transformation. Figure 1(a) shows the original MCG map of the normal heart at QRS 30.0 (ms). Figure 1(b) shows a wavelet spectrum of Fig. 1(a). Figures

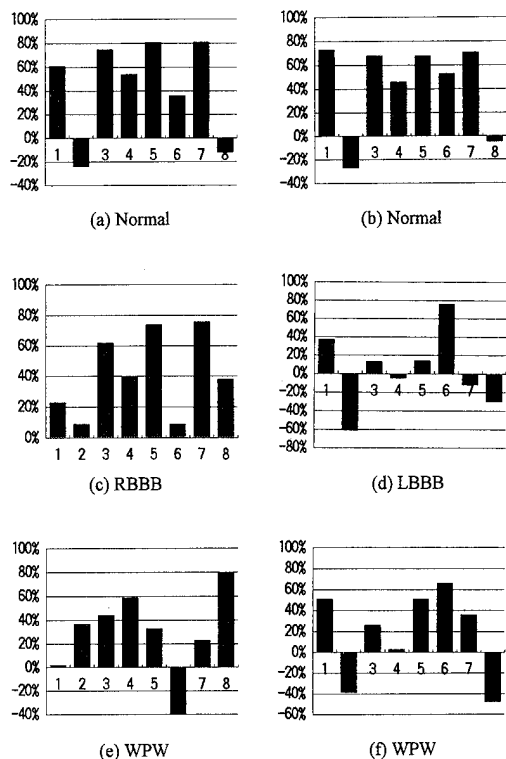

FIG. 3. Examples of the MCG diagnosis by means of the data base approach. (a) The correlative coefficient between the data base and normal heart. Similarly the correlative coefficients to the other normal (b), RBBB (c), LBBB (d), WPW syndromes (e), and the other WPW syndromes (f).

1(c) and 1(d) show the reproduced MCG map from the 100% and 6.25% spectrums in Fig. 1(b), respectively.

The results in Fig. 1 show that the wavelet transformation efficiently compresses the information included in the MCG map.

C. Data base approach

We applied the data compression by the wavelet transformation to the practical MCG maps.

Figures 2(a) and 2(b) show the original MCG map and its compressed wavelet spectrum (6.25%), respectively. We constructed the compressed data base using eight sets of the MCG data of normal hearts.

Figure 3(a) shows the correlative coefficients between the data base and the normal heart. Figures 3(b)–3(f) show the correlative coefficients to the other normal heart, right

FIG. 4. Estimated current distribution in the case of normal heart at QRS 30.0 (ms). (a) An original current distribution, and (b) reproduced current distribution from the 1/16 times compressed data base.

FIG. 5. Estimated current distribution in the case of WPW syndromes at QRS 30.0 (ms). (a) An original current distribution, and (b) reproduced current distribution from the 1/16 times compressed data base.

bundle branch block (RBBB), left bundle branch block (LBBB), Wolff–Perkinson–White (WPW) syndromes, and the other WPW syndromes, respectively.

Consideration of the results in Fig. 3 suggests that the data base approach makes it possible to identify the normal or not normal heart. Further, increasing a number of data bases may improve the accuracy of this approach.

D. Magnetic field source searching approach

In order to improve the data base approach, we evaluated the current distribution of heart from the compressed data base. Our searching strategy of the current distribution is called the sampled pattern matching method, which is a kind of generalized factor analysis.^{2–4}

Figures 4(a) and 4(b) show an original current distribution and its reproduced current distribution from the 6.25% compressed data base, respectively. A similar example is shown in Fig. 5 for the WPW syndromes. Considering the results in Figs. 4 and 5, it is confirmed that the current distribution in the heart can be reproduced with sufficient accuracy from only the 1/16 times compressed data base. This means that further improvement of the heart diagnosis can be carried out by the inverse approach.

III. CONCLUSION

In the present article, we have applied the wavelet analysis to the MCG diagnosis.

At first, we proposed the data base approach using the MCG data compression by wavelet transformation. Using this data base approach, the normal and abnormal hearts could be read off.

Second, applying the magnetic field source searching approach to the compressed data base, the distinct current distribution reveals the details of heart condition. A further increase of the number of data bases should be carried out for the improvement of accurate diagnosis.

Functionalization and applications of nanosized γ -Fe₂O₃ particles

Qingxia Liu and Zhenghe Xu

Department of Mining and Metallurgical Engineering, McGill University, Montreal, P.Q., Canada H3A 2A7

A novel method to prepare nanosized γ -Fe₂O₃ particles containing reactive thio and/or disulphide groups using molecular self-assembly method is described. The monolayers are formed from self-assembled bolaamphiphiles, e.g., 16-mercaptohexadecanoic acid (HS-C₁₅H₃₀-COOH), and characterized using x-ray photoelectron spectroscopy. The magnetization of surfactant-coated particles is determined using a vibrating sample magnetometer. The potential uses of functionalized magnetic particles in recovering precious (Ag⁺) and base (Cu²⁺) metal ions from industrial effluent are examined. The modification of thiol on coated-magnetic particles by controlled oxidation is also described to extend the application of self-assembled organic monolayers to stabilizing ferrofluids.

I. INTRODUCTION

Fine magnetic particles coated with thin organic films have found wide applications in raw material recovery,¹⁻³ biological cell separation,^{4,5} waste remediation,⁶ magnetic fluids,⁷ magnetic ink, and magnetic memory media.⁸ The organic thin films are often prepared by sol-gel silica coating followed by silanation,⁹⁻¹⁰ formation of surfactant bilayers¹¹ and/or vesicles,¹² as well as polymer and ligand adsorption¹³ on magnetic particles. These methods involve complex physical and interfacial chemistry, and the choice of preparation methods depends on the end-use of the prepared particles. The ease of synthesis, and control of the functionality and stability of the organic thin films are three major concerns.

The preparation of organic thin films on magnetic particles with reactive thio groups is of great interest due to their potential applications. It is well known that thio or disulphide groups are readily cross-linked to other incubated antibodies usually containing disulphides in the basic unit, forming tetrameric antibody complexes.¹⁴⁻¹⁶ The simplicity of Langmuir-Blodgett deposition and self-assembly has made these methods useful in preparing various types of thin organic films.¹⁷ In this communication, we report the preparation, characterization, and application of organic thin films containing reactive thio groups on nano-sized γ -Fe₂O₃ particles.

II. EXPERIMENT

A. Monolayer

γ -Fe₂O₃ powder (50 mg) purchased from Alpha Chemicals (20 nm) was gently mixed with 25 mL 16-mercaptohexadecanoic (MHA) solution (3 mM, prepared in chloroform) in a 40 mL vial while bubbling the nitrogen through the solution. The vial was then sealed and shaken for 24 h using a laboratory shaker. The treated particles were separated from solution by a hand magnet and rinsed repeatedly with chloroform, followed by dry hexane to remove unbound surfactant.

B. Oxidation of MHA monolayers

The reactive thio and/or disulphide groups on γ -Fe₂O₃ were further oxidized to produce different functionalities of sulphonate and/or sulphate. The oxidation experiment was

conducted by bubbling ozone through the suspension of MHA-coated γ -Fe₂O₃ particles at a constant temperature of 0 °C for half an hour.

C. Characterization

X-ray photoelectron spectroscopy (XPS) and vibrating sample magnetometer (VSM) were used to characterize the γ -Fe₂O₃ particles with or without surfactant monolayer coatings. The experimental details in XPS spectrum acquisition were given elsewhere.¹⁸ The VSM instrument was calibrated against a single crystal of nickel. The ζ potentials of γ -Fe₂O₃ particles with and without the treatment were also measured in 1 mM KCl solutions using a 501 Lazer-Zee Meter.

III. RESULTS AND DISCUSSION

A. Monolayer characterization

XPS spectra of γ -Fe₂O₃ particles with various treatments are shown in Fig. 1. The appearance of C_{1s} and S_{2p} bands on spectrum *b* (Figs. 1 and 2) for the samples contacted with MHA solutions, compared with spectrum *a* (untreated), suggests the self-assembly of MHA on γ -Fe₂O₃. In our previous report,¹⁸ we have shown, from the semiquantitative XPS analysis using area ratio of bands Fe_{2p} to C_{1s}, that the magnetic particles immersed in MHA solution have a similar surface surfactant coverage to that obtained when γ -Fe₂O₃ is treated with a stearic acid solution. The Fourier transform infrared spectroscopic investigation confirmed that the carboxyl group of MHA is chemically anchored on γ -Fe₂O₃, leaving the thio group free for further reactions. The infrared spectra coupled with critical surface tensions derived from film flotation suggested the formation of a well-ordered and compact surfactant monolayer. It was also found that the MHA monolayer on γ -Fe₂O₃ was stable in acidic and alkaline media.

B. Metal ion loading characteristics

One of the important applications for the MHA coated γ -Fe₂O₃ particles containing reactive thio or disulphide groups is to recover precious (Ag) and base (Cu) metal ions or to remove toxic species from industrial effluents. It is well known that thio and disulphide groups have strong affinity to various metal ions, such as gold, silver, and copper.¹⁹ The fabricated magnetic particles of large surface area can, there-

FIG. 1. XPS spectra of survey scans for $\gamma\text{-Fe}_2\text{O}_3$ surfaces with various treatments: (a) untreated; (b) MHA coated; (c) MHA coated with loaded Cu; and (d) MHA coated with loaded Ag.

fore, be used to capture silver or copper often present in industrial effluent. The metal-loaded magnetic particles can then be readily separated from effluent using magnetic separation.

To examine this application, the MHA-coated $\gamma\text{-Fe}_2\text{O}_3$ particles were brought to the contact with 10 mM CuSO_4 and AgCl solutions. The loaded particles were characterized using XPS spectroscopy and the spectra are included in Fig. 1. The bands centered at 934 and 954 eV on spectrum c (Fig. 2)

are characteristic of copper ions, indicating the adsorption of copper from the solutions. The satellite band at 945 eV suggests that the majority of copper ions are in cupric form (Cu^{2+}) on MHA-coated $\gamma\text{-Fe}_2\text{O}_3$ particles. In addition, the area ratio of cupric satellite band to its $2P_{3/2}$ bands is lower than expected for pure cupric ions, suggesting that some of the copper ions are in a cuprous state. It appears that some cupric ions get reduced as a result of thiol oxidation to disulphide, sulphonate or sulphate, which accounts for the presence of an additional sulphur band of higher binding energy and low intensity (Fig. 2: S). In the case of silver-loaded particles, two bands at 368 and 374 eV are observed (Fig. 1: spectrum d; Fig. 2: Ag), suggesting that silver binds to MHA-coated $\gamma\text{-Fe}_2\text{O}_3$ particles.

The loading efficiency is evaluated by calculating the ratio of band area normalized by the element sensitivity factors. The calculation shows a 60% coverage of surface sulphur by copper ions and 80% by silver ions, demonstrating the potential use of MHA-coated $\gamma\text{-Fe}_2\text{O}_3$ particles in recovery of Ag and Cu from industrial effluent. The results suggest that each silver ion binds with one sulphur on MHA-coated $\gamma\text{-Fe}_2\text{O}_3$ particles. Whether each copper ion binds with two surface sulphurs is not clear. It appears that cuprous ions bind predominately with one while cupric ions bind with two sulphur atoms. This accounts for the low coverage of sulphur by copper ions (60%), yet higher than 50% as expected for a S:Cu coordination of 2:1.

C. Magnetic properties

The room temperature magnetization curve for the $\gamma\text{-Fe}_2\text{O}_3$ particles, obtained on a VSM, is shown in Fig. 3. A saturation magnetization of 52.7 emu/g at 1 Tesla was obtained for untreated $\gamma\text{-Fe}_2\text{O}_3$ particles, representing a strong magnetization. Only a marginal decrease in the saturation magnetization (2 emu/g) was observed when $\gamma\text{-Fe}_2\text{O}_3$ particles are coated with MHA. A common feature of these two magnetization curves is their small hysteresis and coercivity of magnetization, indicating that these particles are close to superparamagnetic at room temperature. It is also possible that the nanosized magnetic particles inverse magnetization by a rigid body rotation, contributing to an observed low coercivity. However, this is unlikely to be the case since the particles were pressed into a pellet form in our VSM experiments. Therefore, the observed low coercivity suggests that nano-sized $\gamma\text{-Fe}_2\text{O}_3$ particles do not become permanently magnetized after exposure to an external magnetic field. This property permits the particles to be redispersed without magnetic aggregation. Hence, the particles may be reused or recycled. It is also interesting to note that the thin organic film coatings do not affect the magnetization characteristics of fine magnetic particles for their use as magnetic memory media.

D. Electrokinetics

Another important application of thin organic film coating on fine magnetic particles is to stabilize magnetic particles in ferrofluid. The untreated $\gamma\text{-Fe}_2\text{O}_3$ particles exhibit an isoelectric point (iep) at $\text{pH} \sim 5$ as shown in Fig. 4 (down

FIG. 2. XPS spectra of narrow scans for the elements of interests on $\gamma\text{-Fe}_2\text{O}_3$ surfaces with various treatments: (a) untreated; (b) MHA coated; (c) MHA coated with loaded Cu; and (d) MHA coated with loaded Ag.

FIG. 3. Room temperature magnetization curve of $\gamma\text{-Fe}_2\text{O}_3$ obtained with vibrating sample magnetometer: solid line for untreated and dotted line for MHA-coated particles.

triangles). The particles tend to coagulate in neutral aqueous solution under the influence of molecular and magnetic attractive forces against the electrostatic double layer repulsive force which is minimal at solution pH's near the iep of the particles. This makes the stability of aqueous ferrofluids in neutral pH quite problematic, requiring the use of stabilizers. The presence of stabilizers may alter the magnetic properties of ferrofluids significantly. It has been shown that the presence of self-assembled thin organic films does not change the magnetization of $\gamma\text{-Fe}_2\text{O}_3$ particles. The ζ -potential measurement showed (Fig. 4: circles) that the iep remained the same while the ζ -potential becomes more negative above the iep when $\gamma\text{-Fe}_2\text{O}_3$ particles are coated with MHA. As a result, only marginal increase in electrostatic double layer repulsive force is expected. However, when the MHA monolayer on $\gamma\text{-Fe}_2\text{O}_3$ gets oxidized with ozone bubbling, the $\gamma\text{-Fe}_2\text{O}_3$ becomes negatively charged over the whole pH range studied (Fig. 4: squares). This may be attributed to the conversion of thiol or disulphide to sulphonate and/or sulphate which are the strong acids and readily dissociated. As a result, the surface retains a surface potential as high as -50 mV (so-called negative magnetic particles), inducing a strong electrostatic repulsive force between particles. This repulsive force can overcome the attractive molecular and magnetic forces. With additional short range hydration repulsion of sulphonate or sulphate groups, stable ferrofluids of high solid content can, therefore, be prepared for various industrial applications.

IV. CONCLUSIONS

The present work demonstrates that the self-assembly method can be used to prepare nanosized magnetic particles of a given functionality. The $\gamma\text{-Fe}_2\text{O}_3$ particles with reactive thio and/or disulphide groups were obtained by self-

FIG. 4. Zeta potentials of $\gamma\text{-Fe}_2\text{O}_3$: down triangles for untreated particles; circle for MHA-coated particles; and square for MHA-coated particles but with further oxidation.

assembly of 16-mercaptohexadecanoic acid (MHA) from chloroform solutions. The presence of surfactant monolayers on $\gamma\text{-Fe}_2\text{O}_3$ has a marginal effect on its magnetization. The functionalized magnetic particles with reactive thio and/or disulphide groups are capable of capturing metal ions from aqueous solution, 80% and 60% of the sulfur being covered by silver and copper, respectively. The functionality of thiol on coated magnetic particles can be further modified by controlled oxidation to extend the application of self-assembled organic monolayers to stabilizing ferrofluids.

Catalytic activity of catalase under strong magnetic fields of up to 8 T

S. Ueno and M. Iwasaka

Institute of Medical Electronics, Faculty of Medicine, University of Tokyo, Tokyo 113, Japan

The question of whether or not magnetic fields affect enzymatic activity is of considerable interest in biomagnetics and biochemistry. This study focuses on whether magnetically related enzymatic activities can be affected by magnetic fields. We examined the effect of magnetic fields of up to 8 T on catalytic decomposition of hydrogen peroxide (H_2O_2). We observed changes in absorbance of reaction mixture of hydrogen peroxide and catalase at 240 nm, during and after magnetic field exposures. When the reaction mixture was not treated with nitrogen-gas bubbling, it was observed that the initial reaction rate of the reaction which was exposed to magnetic fields of up to 8 T was 50%–85% lower than the control data. This magnetic field effect was not observed, however, when the reaction mixture was bubbled with nitrogen gas to remove the dissolved oxygen molecules which were produced in the solution. We also measured concentration of dissolved oxygen which was produced by the decomposition of hydrogen peroxide. Dissolved oxygen concentration in the reaction mixture which was exposed to magnetic fields increased 20%–25% compared to the control solution. The results of the present study indicate that magnetic fields affect dynamic movement of oxygen bubbles which are produced in the reaction mixture by the decomposition of hydrogen peroxide, but not the catalytic activity of catalase itself. © 1996 American Institute of Physics. [S0021-8979(96)49608-3]

I. INTRODUCTION

The question of whether magnetic fields affect enzymatic activity or not is of considerable interest in biomagnetics and chemistry.

Catalase, which is an important heme protein in the body used to decompose toxic hydrogen peroxide, contains a ferric state (Fe^{3+}) iron atom, therefore its magnetic property shows paramagnetism.

It has been reported that magnetic fields of up to 6 T enhanced the activity of catalase 4.9%–52%.^{1,2}

In our former study, however, we observed that magnetic fields of up to 1.0 T did not alter the rate of decomposition of hydrogen peroxide catalyzed by catalase.³ Another group reproduced the negative results of catalase activity at 1.0 T.⁴

Oxygen molecules, which are produced by decomposition of hydrogen peroxide, are paramagnetic. We have reported that the oxygen absorption rates and desorption rates in a solution were modulated by the spatial distribution of oxygen gas in the air.⁵ We have also reported that dissolved oxygen concentration was redistributed in magnetic fields of up to 8 T.⁶

In the present report, we examined the effect of magnetic fields of up to 8 T on catalytic decomposition of hydrogen peroxide (H_2O_2). Change in absorbance at 240 nm and dissolved oxygen concentration were measured.

II. METHOD

We used a horizontal type of superconducting magnet 700-mm long with a bore of 100 mm in diameter. The magnet produced 8 T at its center.

We investigated catalytic decomposition of hydrogen peroxide by catalase in a homogeneous magnetic field of 8 T, and in gradient magnetic fields where products of B and the gradient were 350–400 T^2/m .

A. Absorbance measurement

We carried out two types of experiments to evaluate the activity of catalase by changes in absorbance at 240 nm. The rate of disappearance of hydrogen peroxide was measured by observing the decrease in absorbance at 240 nm:

First, absorbance of hydrogen peroxide was measured before and after an 8 T magnetic field exposure. In this case, low concentrations of catalase solutions were used. The reaction was started by the addition of 5 μl of catalase to 3 ml of hydrogen peroxide. Final concentration of catalase and hydrogen peroxide was 0.0125 μM and 10 mM, respectively. Reaction mixtures were exposed to a magnetic field of 8 T for 80 s at $30^\circ\text{C} \pm 0.1^\circ\text{C}$. After the mixture was removed from the magnetic fields, the absorbance of the mixture at 240 nm was immediately measured with a spectrophotometer.

The rate of reaction was evaluated by the reaction velocity constant $k = (1/t) \ln(c_0/c_1)$, where t is the reaction time, c_0 the initial absorbance, and c_1 the absorbance of the solution after t s.

Second, changes in the absorbance of hydrogen peroxide were measured during the 8 T magnetic field exposure. We made an absorbance measuring system in the superconducting magnet, as shown in Fig. 1. Rays from a deuterium lamp were introduced into the bore of the magnet. A reaction mixture in a cell with 1 cm optical path was kept in a temperature stabilized holder ($25^\circ\text{C} \pm 0.1^\circ\text{C}$). Rays penetrated the cell and were introduced into an optical fiber which was connected to a monochromator.

Absorbance of the reaction mixture at 240 nm was continuously measured with and without nitrogen-gas bubbling. In order to de-gas oxygen bubbles and stir the reaction mixture, the nitrogen-gas bubbling was carried out by introduc-

FIG. 1. Experimental setup to measure absorbance of a reaction mixture in magnetic field.

ing nitrogen gas into the reaction mixture. Final concentration of catalase and hydrogen peroxide was $0.03\text{--}0.3\text{ }\mu\text{M}$ and $2.5\text{--}50\text{ mM}$, respectively.

We also measured the decomposition of hydrogen peroxide by catalase in gradient magnetic fields where products of B and the gradient were $350\text{--}400\text{ T}^2/\text{m}$.

B. Dissolved oxygen measurement

The rate of the decomposition of hydrogen peroxide by catalase was evaluated by the amount of dissolved oxygen concentration. A reaction mixture in a 50-ml beaker (30 ml hydrogen peroxide and $20\text{ }\mu\text{l}$ of catalase) was incubated in the thermal stabilization case, with and without an 8 T magnetic field. The final concentration of catalase and hydrogen peroxide was 3 nM and 30 mM , respectively. After $3\text{--}40\text{ min}$ of incubation at $25\text{ }^\circ\text{C} \pm 0.2\text{ }^\circ\text{C}$, a reaction mixture was taken out from the thermal stabilization case. Dissolved oxygen concentration was measured with a Clark type dissolved oxygen meter.

III. RESULTS AND DISCUSSION

The reaction velocity constant k of samples exposed to an 8 T magnetic field and control samples ($n=13$) was $1.2 \pm 0.1 [\times 10^{-3}]$ and $1.3 \pm 0.2 [\times 10^{-3}]$, respectively, as shown in Fig. 2.

Figure 3(a) shows the changes in the absorbance of hy-

FIG. 2. Decomposition of hydrogen peroxide by catalase. Vertical line shows reaction velocity constant $k = (1/t) \ln(c_0/c_1)$, where $t=80\text{ s}$, c_0 the initial absorbance, and c_1 the absorbance of the solution after 80 s.

FIG. 3. Changes in the absorbance of hydrogen peroxide (a) without and (b) with nitrogen-gas bubbling. Catalase concentration was $0.03\text{ }\mu\text{M}$. Hydrogen peroxide concentration was (a) 50 mM and (b) 20 mM .

drogen peroxide without nitrogen-gas bubbling. It was observed that initial reaction rate in magnetic fields of up to 8 T was 79% lower than the control. However, as shown in Fig. 3(b), this kind of positive effect of magnetic fields on initial reaction rate was not obtained in the condition with nitrogen-gas bubbling.

Figure 4 shows double reciprocal plots of the initial reaction rate v and the substrate concentration $[S]_0$ in the decomposition of hydrogen peroxide by catalase with and without nitrogen-gas bubbling. Similar to the results in Fig. 3, magnetic fields of up to 8 T affect the initial reaction rate v

FIG. 4. Double reciprocal plots of the initial reaction rate v and the substrate concentration $[S]_0$ in the decomposition of hydrogen peroxide by catalase (a) without and (b) with nitrogen-gas bubbling. V_{max} is the maximum initial rate, and K_m is the Michaelis constant.

FIG. 5. Dependence of initial reaction rate on concentrations of catalase.

when the reaction proceeds without nitrogen-gas bubbling. The maximum initial rate V_{\max} in magnetic fields is $\frac{1}{7}$ of the control.

In contrast, we obtained clear negative results with nitrogen-gas bubbling.

Dependence of initial reaction rate on concentrations of catalase is shown in Fig. 5. The data were obtained with nitrogen-gas bubbling. No significant effects were observed.

The results in Figs. 3 and 4 indicate that oxygen molecules which are produced by decomposition of hydrogen peroxide disturb the reaction significantly. Ejection of dissolved oxygen by nitrogen-gas bubbling removes the effects. There is a possibility that the magnetic fields restrain the evaporation of dissolved oxygen molecules from a reaction mixture.

It is necessary to investigate the changes in concentration of dissolved oxygen in reaction mixture. Figure 6 shows the results of dissolved oxygen measurement. No significant effects were observed during 3–5-min and 35–50-min period after the addition of catalase. On the other hand, dissolved oxygen concentration of the mixture which was exposed to an 8 T magnetic field increased 20%–25% compared to the control during a 10–20-min period.

We observed that the decomposition process of hydrogen peroxide catalyzed by a high concentration catalase generated visible oxygen bubbles. Aggregated visible oxygen bubbles can be attracted by strong magnetic fields with high gradients.⁶ We have observed that dissolved oxygen concentration was redistributed in magnetic fields of up to 8 T.⁶ We also observed that the oxygen desorption rate in a solution

FIG. 6. Effect of magnetic field at 8 T on dissolved oxygen concentration which was generated by the decomposition of hydrogen peroxide by catalase.

was modulated by the spatial distribution of oxygen gas in the moist atmosphere.⁵

If a process of enzymatic reactions involve a radical pair, there is the possibility that magnetic fields affect the singlet-triplet conversion rate of radical pairs. The enzymatic reactions which involve photochemical processes are the most promising magnetically sensitive enzymatic reactions. The magnetic field effects on photochemical reactions were verified.^{7–9}

Apart from the photochemical reactions, it is important to study the enzymatic reactions that involve radicals which are generated from nonphotochemical processes. It has been reported that magnetic fields of 0.10–0.15 T affected B_{12} ethanolamine ammonia lyase.¹⁰

The results of the present study indicate that magnetic fields of up to 8 T affect the dynamic movement of oxygen bubbles which are produced in the reaction mixture by hydrogen peroxide decomposition, but not the catalytic activity of catalase itself.

Fibrin polymers, as a kind of diamagnetic material, are oriented parallel to the direction of magnetic fields. We investigated the polymerization of partially digested fibrinogens in an 8 T magnetic field in order to observe the clotting ability of various sizes of fibrinogen fractions using a magnetic orientation technique. We purified high-molecular weight fraction (F1) and low-molecular weight fraction from human fibrinogen (F2). Fibrin gels were formed in an 8 T magnetic field for 9 h, and transmittancies were measured to evaluate the degree of magnetic orientation. The results show that a lack at the C-terminal half of one A α chain did not affect the magnetic orientation of fibrin. We also investigated the effect of the digestion of fibrinogen by plasmin on the magnetic orientation of fibrin. The result shows that partially digested fibrin molecules also orient in an 8 T magnetic field. However, the degree of magnetic orientation significantly decreases when fragment X and fragment Y appear. © 1996 American Institute of Physics. [S0021-8979(96)49708-X]

I. INTRODUCTION

In the last process of blood coagulation, fibrinogen molecules change to fibrin monomers through the action of pro-enzyme thrombin. Fibrin monomers are polymerized and form various sizes of fibers to become a gel. A fibrinogen molecule is a kind of diamagnetic material which has diamagnetic anisotropy. In the course of the polymerization process of fibrin, when a magnetic field of 10 to 20 T intensity is applied, the fibrin fibers orient parallel to the magnetic fields.¹⁻³ Some studies reported on the mechanisms of the polymerization process using the magnetic orientation of fibrin.⁴⁻⁶ To investigate the fibrin structure and the mechanism of fibrin assembly, effects of coagulation factors such as Ca²⁺, factor XIIIa, the fibrinopeptides on magnetic orientation of fibrin were clarified.^{4,6} It was reported that ferromagnetic particles affected the magnetic orientation of fibrin polymers.³ We have reported that magnetic orientation of fibrin fibers is observed in the fibrinolytic process.⁷

However, effects of degradation of fibrinogen molecules on magnetic orientation are not clear.

In this study, we investigated the polymerization of partially digested fibrinogens in an 8 T magnetic field in order to observe the clotting ability of various sizes of fibrinogen fractions using a magnetic orientation technique.

A fibrinogen molecule has three types of polypeptide chains. Each chain has the important role of binding other fibrin molecules. A simplified model of a fibrinogen molecule is shown in Fig. 1.⁸ It is known that there are two types of fibrinogen fractions: high-molecular weight fractions and low-molecular weight fractions which lack the C-terminal half of one of the A α chain that is one of three types of chains.⁹ It is an interesting question whether the C-terminal half of one of the A α chain has any effect on the magnetic orientation of fibrin.

II. MATERIALS AND METHODS

A. Magnetic field exposure system and measurement of magnetic orientation

We used a horizontal type of superconducting magnet 700 mm long with a 100 mm diameter bore. The magnet produced magnetic fields of up to 8 T at its center.

We used a spectrophotometer to observe the magnetic orientation of fibrin. Polarizing plates were placed before and after the optical cell holder, as shown in Fig. 2. The polarizing angle of the plate placed after the optical cell holder was

FIG. 1. Simplified model of a fibrinogen molecule and fractions. (a) Two types of fibrinogen fractions: high-molecular weight fractions and low-molecular weight fractions which lack the C-terminal half of one of the A α chain that is one of three types of chains. (b) Fragment X and fragment Y.

FIG. 2. Experimental setup to measure magnetic orientation of fibrin polymers.

0°, and the plate placed before the optical cell holder was 60°.

When fibrin polymers in an optical cell were oriented in a particular direction, optical anisotropy was observed as the difference of transmittancies (ΔT [%]) through two sides of the cell. This is a modulated method for measuring magnetic birefringence.¹⁰ We measured two types of transmittancies of fibrin gel in a cell. One was the transmittance when the direction of light was parallel to the direction of the magnetic orientation of fibrin, and the other was the transmittancy when the direction of light was vertical to the direction of the orientation of fibrin. Fibrin gels were formed in an 8 T magnetic field for 9 h, and ΔT was measured to evaluate the degree of magnetic orientation.

B. Preparation of high- and low-molecular weight fraction from human fibrinogen

We purified high-molecular weight fraction (F1) and low-molecular weight fraction (F2) from human fibrinogen, according to the method reported by Hasegawa *et al.*¹¹

C. Digestion of bovine fibrinogen with plasmin

We also investigated the effect of the digestion of fibrinogen by plasmin on the magnetic orientation of fibrin. Fibrinogen solutions (3.7, 1.5, and 0.66 mg/ml) were incu-

TABLE I. Magnetic orientation of two types of human fibrin. DT of F1 rich solution (F1:F2=9:1) and F2 rich solution (F1:F2=1:9).

Group	F1:F2	Concentration [mg/ml]	ΔT at 633 nm [%]
F1 rich	9:1	0.21	5.4
F2 rich	1:9	0.20	5.8

FIG. 3. Magnetic orientation of partially degraded bovine fibrin polymers. Concentration of fibrinogen was 3.7 mg/ml. Final concentration of plasmin varied from 0.016 to 0.16 [caseinolytic units/ml].

bated with various concentrations of plasmin or without plasmin for 7 min at 37 °C. Each solution was mixed with 1 ml of tranexamic acid to stop the digestion of fibrinogen.¹² After fibrin gels were coagulated in an 8 T magnetic field, the ΔT of each gel was measured.

III. RESULTS AND DISCUSSION

Human fibrinogen solutions (0.2 mg/ml) were incubated with 5 μ l of thrombin (5 NIH units/ml). ΔT of F1 rich solution (F1:F2=9:1) and F2 rich solution (F1:F2=1:9) was 5.4% and 5.8%, respectively, as shown in Table I. The results show that a lack of the C-terminal half of one A α chain did not affect the magnetic orientation of fibrin.

Low-molecular weight fraction (F2) only lacks the C-terminal half of one of the A α chain that is one of three types of chains. We investigated the magnetic orientation of bovine fibrinogen fractions which were further digested than the F2 fraction.

Figure 3 shows the results of magnetic orientation measurement of bovine fibrinogen fractions. It was observed that ΔT decreased depending on the amount of plasmin. When the final concentration of plasmin was more than 0.160 [caseinolytic units/ml], ΔT was zero.

Table II shows the results in the range of fibrinogen concentration from 0.66 mg/ml (C,D) to 1.45 mg/ml (A,B). Plasmin concentrations were 10 [$\times 10^{-3}$ caseinolytic units/ml] for A and C samples, 30 [$\times 10^{-3}$ caseinolytic units/ml] for B

TABLE II. Critical conditions for observing magnetic orientations of fibrin polymers. Fibrinogen-plasmin ratio shows the ratio of fibrinogen concentration [mg/ml] to plasmin activity [caseinolytic units/ml].

Sample	A	B	C	D
Fibrinogen concentration [mg/ml]	1.45	1.45	0.66	0.66
Plasmin concentration [caseinolytic units/ml]	0.01	0.03	0.01	0.05
Fibrinogen-plasmin ratio [mg/caseinolytic units]	145.0	48.3	66.0	13.2
ΔT at 633 nm [%]	3.9	1.4	2.3	0.1

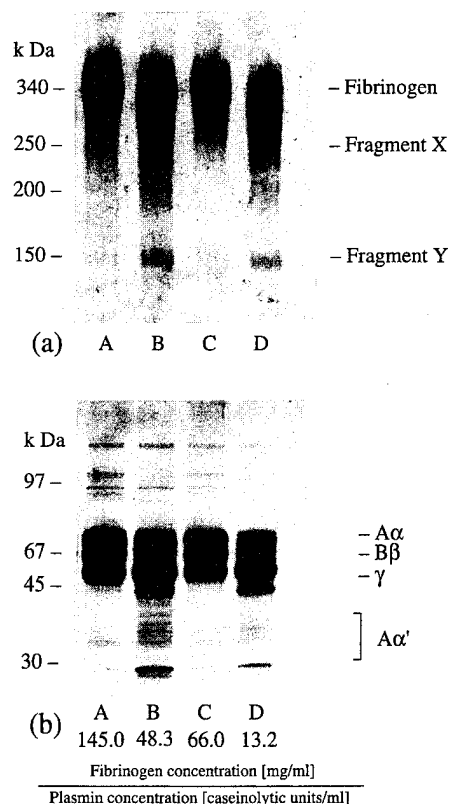

FIG. 4. SDS-PAGE of the degradation products of fibrinogen produced by plasmin. Same samples are shown in Table II. (a) Under nonreducing condition (4% gel), (b) under reducing condition (10% gel).

sample, and 50×10^{-3} caseinolytic units/ml] for D sample. The fibrinogen–plasmin ratios show fibrinogen concentration [mg/ml]/plasmin activity [caseinolytic units/ml]. Depending on the fibrinogen–plasmin ratio, ΔT changed, and reached almost zero when the fibrinogen–plasmin ratio was 13 [mg/caseinolytic units]. This condition is critical in observing the magnetic orientation of partially digested fibrinogen.

Figure 4 shows the results of an SDS-PAGE (Polyacrylamide Electrophoresis) analysis of partially digested fibrinogens which were the same samples in Table II. Figure 4(a) shows the SDS-PAGE patterns of fibrinogen fractions under nonreducing conditions.

It was observed that magnetically oriented fibrinogens (A, and C samples) have a molecular weight of more than 200 kD. On the other hand, magnetically nonoriented fibrinogen molecules (D sample) also include so-called fragment X, and fragment Y. Although sample B included fragment X and fragment Y, concentration of sample B (1.45 mg/ml) is higher than in sample D (0.66 mg/ml). Degree of magnetic orientation of sample B (1.45 mg/ml) was lower than that of sample C (0.66 mg/ml). The results show that degree of magnetic orientation depends not only on the size of fibrinogen fractions, but also on fibrinogen concentration.

The electrophoresis pattern of fibrinogens under reducing conditions in Fig. 4(b) shows that fibrinogen fractions, which did not magnetically orient, mainly consisted of $A\alpha'$, $B\beta$, or γ chains.

The result indicates the level of the size of digested fibrinogen fractions which oriented parallel to the direction of magnetic fields. Partially digested fibrin molecules oriented in an 8 T magnetic field. However, the degree of magnetic orientation decreased when the amount of fragment X and fragment Y, which are produced by degradation of fibrinogen, increased.

Usually, clottability of fibrinogen is evaluated by measuring absorbance of coagulating fibrin at 350 nm. We measured the absorbance of samples shown in Fig. 4 at 350 nm. However, the difference of absorbance in the samples were smaller than 0.01 [OD]. In our experimental setup, optical anisotropy ΔT is proportional to the degree of magnetic orientation. Table II and Fig. 4 indicate that degree of magnetic orientation varies inversely with the degradation of fibrinogen.

Results of the present study suggest that it is possible to estimate the size and function of fibrinogen fractions in a polymerization process using a magnetic orientation technique more sensitively than measuring absorbance changes at 350 nm.

IV. CONCLUSION

We investigated the magnetic orientation of degraded fibrinogen fractions which were produced by plasmin. We observed that optical anisotropy—the degree of magnetic orientation—decreased with the digestion of fibrinogen by plasmin.

Results of SDS-PAGE analysis indicate that the degree of magnetic orientation significantly decreases when fragment X and fragment Y appear.

One of the advantages of neural magnetic measurement using a dc-SQUID machine is to measure magnetic fields associated with the direct current or the extremely low frequencial components of neural electric activities. In this study, the order of four tones is memorized by the subject and compared with that of another four tones. The extremely slow magnetic fields were observed by using this paradigm. Two kinds of tones (two octaves apart: the 1046.5 Hz tone and the 261.6 Hz tone) were used. A male subject memorized the order of four tones chosen randomly. After 1.4 s rest, the other four tones were presented. The subject discriminated the order of the first tones from that of the last tones in the forward order. When another long (1 s) tone was presented 2.4 s later, the subject was to push either a true or a false button. Pushing the true button meant the order of the first four tones was the same as that of the last in the forward order. Pushing the false button meant the order was not the same. The whole-cortex 64 channels of MEG data were digitized with a sampling frequency of 125 Hz, and filtered (zero phase shift, low pass digital filter with a cutoff at 20 Hz). In comparison with the control wave, the wave during memorizing clearly includes very low frequency components. We observed that the intensities of the power spectral components at 0.5 Hz during memorizing and recognition is higher than that of the control power spectral components, and tried to make the topographies using the differences between the power spectral components at 0.5 Hz during memory and recognition and the control power spectral components. Because the memory processes affect the very low frequency components of MEG, the current dipole source models are made from the data filtered below 0.5 Hz. We observed that the memory processes affected the very low frequency components of MEG. We estimated the current dipole sources using MEG data below 0.5 Hz. © 1996 American Institute of Physics. Artifacts in magnetic resonance imaging from metals

L. H. Bennett, P. S. Wang, and M. J. Donahue

National Institute of Standards and Technology, Gaithersburg, Maryland 20899

Metallic biomedical implants, such as aneurysm clips, endoprostheses, and internal orthopedic devices give rise to artifacts in the magnetic resonance image (MRI) of patients. Such artifacts impair the information contained in the image in precisely the region of most interest, namely near the metallic device. Ferromagnetic materials are contraindicated because of the hazards associated with their movement during the MRI procedure. In less-magnetic metals, it has been suggested that the extent of the artifact is related to the magnetic susceptibility of the metal, but no systematic data appear to be available. When the susceptibility is sufficiently small, an additional artifact due to electrical conductivity is observed. We present an initial systematic study of MRI artifacts produced by two low susceptibility metals, titanium (relative permeability $\mu_r \approx 1.0002$) and copper ($\mu_r \approx 0.99998$), including experimental, theoretical, and computer simulation results. © 1996 American Institute of Physics. [S0021-8979(96)49808-4]

The recent report¹ of a fatal outcome when magnetic resonance imaging (MRI) was performed on the head of a patient having a ferromagnetic intracerebral aneurysm clip in place reemphasized the importance of the magnetic properties of clips or other surgical materials placed in the human body. Currently, most of the clips and many of the other implants are made of nonferromagnetic materials. Even so, when a patient with a “nonmagnetic” metal in the body is subjected to a MRI, an artifact is produced which causes a drop-out of signal near the metallic surface. This is an unfortunate circumstance, making it impossible to investigate a treated aneurysm, as the signal is degraded in precisely the region of most interest to the surgeon.

The artifacts produced in MRI by material magnetic susceptibility have been widely studied. For example, Patton² provides an overview of MR imaging and artifacts, and Lüdeke, Röschmann, and Tischler³ give a particularly complete discussion of susceptibility related effects caused by (nonconducting) spheres and cylinders. A recent study⁴ reports on the influence of small quantities of iron particles on MR images, and includes a comparison of the size of the artifact as a function of the particle mass. There has been less attention paid to MRI artifacts caused by eddy currents, but such effects have been observed.^{5,6}

In this paper we report on artifacts in proton MR imaging produced by nonferromagnetic metals in an aqueous medium, including both experimental and theoretical results. In addition to an effect from the material susceptibility, we also observed an artifact caused by eddy currents in the metal. For materials with extremely low susceptibility (e.g., copper), the eddy current effect is the dominant artifact. For materials with a slightly larger susceptibility (e.g., titanium), both susceptibility and eddy current artifacts can be observed. The importance of the object's geometry on the extent of the susceptibility-induced artifact is also demonstrated. In particular, we show and explain how increasing the length of a Ti rod can decrease the MRI artifact (a similar effect was reported but not explained in Ref. 4), and give rise to a bimodal free induction decay frequency response.

The nuclear MR (NMR) imaging facility consists of a Bruker MSL-400 system with micro-imaging accessories.

The spectrometer has a superconducting magnet of 9.394 T which corresponds to a ¹H resonant frequency of ≈ 400 MHz. A set of gradient coils generates field gradients of 9.785×10^{-2} , 3.549×10^{-2} , and 1.175×10^{-2} T/m along the *x* (reading), *y* (phase encoding), and *z* (slicing) axes, respectively. A 15-mm-wide by 30-mm-high rf coil was used for detecting nuclear spin-echo signals of the aqueous protons, with a $(\pi/2)-\tau-\pi-\tau$ echo pulse sequence. More details on the experimental setup can be found elsewhere.⁷

We report here on experiments with 2-mm-diam copper and titanium rods of various lengths, submerged in water inside a 9-mm-inner-diam NMR tube. The applied field was shimmed initially for best response with the NMR tube and water alone. The shimming was left untouched for the rest of the experiments. Each rod was aligned with its long axis parallel to the static field (i.e., along the *z*-axis), and was held in place at the lower end with a teflon disk. The position of the lower end of each rod was the same, with the longer rods extending farther up the NMR tube. The magnetic resonance images were taken with the *z*-coordinate slice height in the center of the detection coil, about 7 mm from the rod's lower end.

We imaged copper rods of lengths between 4 and 25 mm. The (diamagnetic) susceptibility χ_v of the material was -2×10^{-5} (SI—Système Internationale), and the resistivity was 17 $\mu\Omega$ mm. The Fourier transform of the NMR free induction decay consisted of a single peak, and the MRI was essentially independent of the bar length. A representative image for a 15 mm Cu rod is shown in Fig. 1(a). The dark areas indicate the presence of water, so in the absence of any artifact the image would show the cross section of the copper rod as a 2 mm white disk centered inside a 9 mm black annulus of water. The white area here is larger than the rod, and has in particular a notable four-lobe asymmetry. The low susceptibility and high conductivity of the copper and this asymmetry led us to suspect the artifact was due to eddy currents in the copper.

To test this conjecture, we imaged titanium rods of various lengths. The susceptibility of the titanium was 2×10^{-4} (SI), and the resistivity was 530 $\mu\Omega$ mm. Compared to the copper, the titanium is paramagnetic with $|\chi_v|$ 10 times larger, and the resistivity is over 30 times greater. Figure 1(b)

FIG. 1. Experimental results: (a) MR image cross section of a 15 mm Cu rod, (b) an 8 (mm) Ti rod, and (c) a 13 mm Ti rod; (d) Fourier transform of free induction decay for the 8 and the 13 mm Ti rods.

shows the MRI of an 8 mm Ti rod, at a cross-sectional height 1 mm below the top of the rod. Notice the circular susceptibility artifact (the white region is about 4.5 mm across, more than twice the diameter of the bar). Compare this to Fig. 1(c), which represents a cross section near the center of a 13 mm Ti rod. The artifact has a (this time dark) circular component, but exhibits mainly a four-lobe shape similar in size to that seen in the copper rod. We surmise that the symmetric susceptibility artifact is decreased because the slice is taken at a greater distance from the pole faces (i.e., the ends of the bar), and that the four-lobe artifact due to eddy currents is present in both the 8 and 13 mm Ti bar images, but is hidden in the former by the larger susceptibility artifact.

As discussed in the introduction, it is understood that material susceptibility will distort the field uniformity, and also that this can lead to a broadening of the free induction decay linewidth. We are apparently the first to report a splitting of the frequency response, as illustrated in Fig. 1(d), which is the Fourier transform of the free induction decay signal for the two Ti rod experiments. Both graphs show two peaks, but the second peak is more pronounced for the 13 mm rod. This phenomenon is examined in greater detail below.

These experimental results give strong evidence that metal objects produce MRI artifacts of two distinct natures, one due to the material's susceptibility and the second due to its conductivity. To explain these results in more detail, we developed a simple model, implemented that model as a computer simulation, and then compared the simulation results with the experiments. This model explains the observed artifacts by field inhomogeneities alone. It has two components, the first models material susceptibility effects and the

second models eddy current effects. Alternately, these may be considered effects associated with the static field and the rf field, respectively.

The susceptibility effects are modeled by a pair of monopoles, one at each end of the cylindrical rod. For an applied static field of strength B_0 oriented along the positive z axis, the z component of the resultant field at point (x, y, z) is

$$B_z^{\text{static}} = B_0 + \frac{B_0 \chi_v R^2}{4} \left(\frac{z - z_t}{[x^2 + y^2 + (z - z_t)^2]^{3/2}} - \frac{z - z_b}{[x^2 + y^2 + (z - z_b)^2]^{3/2}} \right), \quad (1)$$

where χ_v is the material susceptibility, R is the radius of the bar, and z_t and z_b are the z coordinates of the top and the bottom of the bar, respectively. For nonferromagnetic materials the relative contributions of the in-plane components B_x and B_y are small enough to be neglected.

For this initial study we used a simplified eddy current model. First, replace the finite rod with an infinite cylinder, and then notice that at the frequencies of our rf pulse (400 MHz) the skin depth $\delta = (f\pi\mu\sigma)^{-1/2}$ for metals is in the micron range ($\delta_{\text{Cu}} = 3.3 \mu\text{m}$, and $\delta_{\text{Ti}} = 18 \mu\text{m}$). The eddy currents set up a magnetic field that exactly opposes the applied rf field below about one skin depth. Since the skin depth is negligible compared to the diameter of the rod (2 mm), our cylinder can be approximated by a cylinder that is uniformly magnetized directly equal but opposite to the applied rf pulse. For an applied pulse parallel to the y axis with amplitude $B_{\text{applied}}^{\text{rf}}$, the resultant field at position (x, y) has amplitude components

$$B_x^{\text{rf}} \approx -2xyB_{\text{applied}}^{\text{rf}}R^2(x^2 + y^2)^{-2}, \quad (2)$$

$$B_y^{\text{rf}} \approx B_{\text{applied}}^{\text{rf}}[1 + R^2(x^2 - y^2)(x^2 + y^2)^{-2}], \quad (3)$$

where R is again the radius of the bar. Note that unlike the equations for B^{static} , B^{rf} does not exhibit circular symmetry.

The static components of the field affect slice and line selection. Field inhomogeneities can shift the effective position (i.e., as seen by the reconstruction) of protons, increasing the apparent density in some regions and decreasing it in others. This effect is evident in Fig. 1(b), where the white artifact is a false indication of a decrease in the proton density, and in Fig. 1(c) where there are regions near the bar that are even darker than the undisturbed regions near the edge of the NMR tube. (For a detailed discussion of this effect see Ref. 3.) Conversely, B^{rf} does not affect slice or line selection, but rather only changes the strength of the rf pulse seen by each proton. If the rf pulse is optimized to give maximal response in the absence of eddy current counterfields, then this effect can only reduce the apparent density at any location. For a first approximation, we modeled the attenuation factor of the spin echo signal by

$$\alpha = -\sin(1.5|B^{\text{rf}}|/\pi B_{\text{applied}}^{\text{rf}})$$

for $\pi < 1.5|B^{\text{rf}}|/\pi B_{\text{applied}}^{\text{rf}} < 2\pi$, and 0 otherwise. For small deviations from $B_{\text{applied}}^{\text{rf}}$ this is the in-plane component of the nuclear magnetization moment resulting from a 1.5π rf pulse.

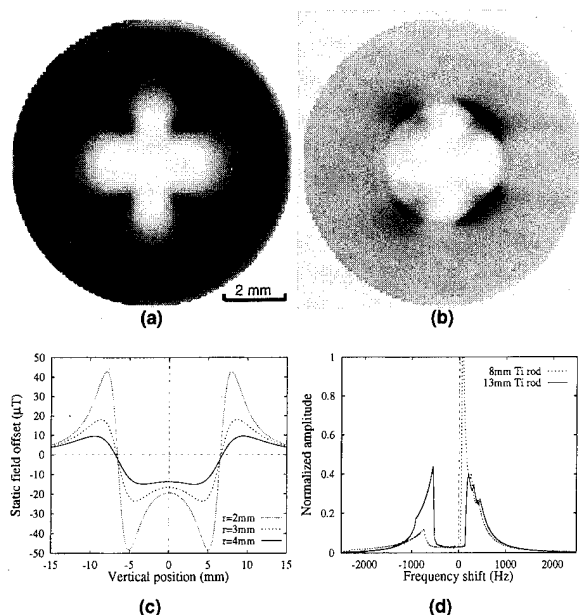

FIG. 2. Theoretical results: (a) Simulated MR image cross section of a 15 mm Cu rod, and (b) a 13 mm Ti rod; (c) field strength B^{static} for 13 mm Ti rod along lines parallel to the z axis at radial distances $r=2, 3$, and 4 mm; (d) simulated Fourier transform of free induction decay for 8 and 13 mm Ti rods.

The forward portion of the computer implementation (simulation of the MR data) was accomplished by partitioning the experimental volume into 0.1 mm cubic voxels, adjusting the proton densities of each voxel according to B^{rf} and the corresponding attenuation factor, and then using Eq. (1) to determine line slice (raysum) selection. Once the data were completely generated, the inverse portion of the simulation—the image reconstruction—was accomplished using a Bracewell convolution filter.⁸

Figures 2(a) and 2(b) show the resulting simulations corresponding to the 15 mm Cu and the 13 mm Ti rod experiments. A simulation of the 8 mm Ti rod experiment was also performed but is not shown. The simulations are all in qualitative agreement with the experiments. Furthermore, by running the simulation with either the susceptibility term or the eddy current term, we have verified that the four-lobe artifact is explained by eddy currents, and that the susceptibility artifact for an MR image taken in the middle of a rod will decrease with increasing rod lengths.

Let us now investigate the resonance splitting in the free induction decay observed in Fig. 1(d). If we use Eq. (1), fix $r = \sqrt{x^2 + y^2}$ and allow z to vary, we obtain line profiles of the field strength along lines parallel to the z axis, as illustrated in Fig. 2(c) for a 13 mm Ti rod, where the applied field B_0 has been subtracted off. The field values at z heights near the center of the bar and also above and below the bar do not vary very much with in-plane distance r from the bar. The middle plateau corresponds to a field value of ≈ -15 μT , and the outside regions level off at ≈ 5 μT . These correspond to

resonance frequencies of ≈ -640 and 210 Hz off the nominal resonant frequency of 400 MHz, not too different from the frequencies of the peaks seen in the experimental free induction decay frequency response curve of Fig. 1(d). A more accurate simulation based on Eq. (1) (taking into account, for example, the appropriate radial weighting) produces the curves presented in Fig. 2(d), and explains the relative size of the peaks as a function of the rod length.

We have shown, via both experiment and theory, that MRI artifacts from metallic objects have two distinct origins and manifestations. The first artifact source is inhomogeneity in the static field due to the material susceptibility, causing the MRI algorithm to mismatch the reconstruction region. When the material susceptibility is small, a second type of artifact becomes important. This artifact type is a result of eddy currents set up in conductors by the high-frequency rf pulses, creating magnetic counterfields which change the effective amplitude of the rf pulses across the imaging region, thereby modifying the spin-echo signal and affecting the image reconstruction.

The susceptibility induced artifact has been extensively studied by others, and it is well understood that the magnitude of this effect scales with the material susceptibility. The importance of the object's geometry has perhaps not been properly appreciated, however. We show, for example, that the artifact produced in the center of a paramagnetic cylindrical rod is actually reduced by making the rod longer. Similarly, it has been understood that the susceptibility induced inhomogeneity can broaden the free induction decay resonance peak. We have shown that the field inhomogeneity from a simple rod can actually create a bimodal resonance response, and that this effect will vary with the length of the rod.

From a design standpoint, since the susceptibility induced artifact can be reduced by minimizing the susceptibility of the metallic part, one might hope to manage the eddy current induced effect by reducing the object's electrical conductivity. Note, however, that the magnitude of this effect scales with the object's width minus the skin depth. The skin depth at 400 MHz of even a relatively poor (for a metal) conductor like Ti is only 18 μm , so the impact of a metal's relative conduction on the size of the artifact is minimal.

We thank H. J. Brown for assistance with measurements and D. E. Mathews for assistance with sample preparation.

Magnetic phase transitions in perovskite-type anilinium-based tetrachlorocuprates

D. J. Nelson, K. Chan, F. Cervantes-Lee, and L. W. ter Haar

Department of Chemistry, University of Texas at El Paso, El Paso, Texas 79968

Our research efforts have expanded upon the work previously done on the molecular composites $(RNH_3)_2CuCl_4$ (R =alkyl-) by utilizing various para-substituted anilines and anilinium derivatives as design tools. The resulting structures have the general formula $(RC_6H_4NH_3)_xCuCl_4$ (R =methyl-, fluoro-, O_2N -, for $x=2$; $R=H_3N$ -, $H_3NC_6H_4$ - for $x=1$) and are similar to the aforementioned compounds, consisting of two-dimensional layers of corner-sharing $CuCl_6$ octahedra, resulting in a type of perovskite lattice. Equivalent magnetic sites are eclipsed between layers in the case of a small interleaving organic moiety, such as $H_3NC_6H_4NH_3$, but are otherwise staggered along one or more axes. Powder susceptibility data for representative compounds containing small anilinium derivatives reveal magnetic transitions at temperatures ranging from ~ 11.5 to ~ 7 K, depending upon the chemical nature of the anilinium substitution and the interlayer spacing. © 1996 American Institute of Physics. I. INTRODUCTION

Research on the magnetostructural correlations of transition-metal ion clusters has been extensive over the past several years.¹ A significant area of this research has been the investigation of low-dimensional magnetic systems and how well these systems conform to present theory.² One area of this research that is still controversial is the nature of the low-temperature magnetic phase transitions occurring in two-dimensional ferromagnetic Heisenberg lattices.³ The best synthetic examples of this theoretical system are the $(RNH_3)_xCuCl_4$ perovskite compounds where R is an alkyl or alkylammonium group ($x=2$ or 1, respectively).⁴ While this series of compounds appears to be exhaustively studied, we have wondered what magneto-optical properties these two-dimensional lattices would exhibit if organic dyes were used as the cationic spacers. Since most dyes are anilinium in nature, we decided to begin our investigations utilizing anilinium derivatives, some structures having already been solved.^{4,5} This work deals with the structural and magnetic properties of the perovskite molecular composites $(RC_6H_4NH_3)_xCuCl_4$ (R =methyl-, fluoro-, and nitro- for $x=2$; $R=H_3N$ -, $H_3NC_6H_4$ - for $x=1$), which represent the first compounds toward dye inclusions.

II. EXPERIMENT

The title compounds were synthesized via slow evaporation of solutions consisting of $CuCl_2 \cdot 2H_2O$ and the appropriate aniline in a 2:1 molar ratio utilizing a solvent with variable proportions of 95% ethanol and concentrated HCl, dependent upon the aniline. All products crystallized out as small, light yellow platelets, with the exception of the 4-phenylenediaminium analog, which crystallized as dark yellow platelets, and the 4-nitroanilinium analog, which crystallized as green square platelets with two opposing corners of each platelet truncated. The crystal structures for the 4-nitroanilinium and phenylenediaminium analogs were determined at room temperature on a Siemens R3m/V four-circle diffractometer with graphite monochromated Mo $K\alpha$ radiation ($\lambda=0.71073$ Å). The Siemens SHELXTL PLUS soft-

ware package was used for structural refinement, utilizing the full-matrix least-squares method⁶ (see supplementary material for solution and refinement parameters). Powder x-ray diffraction was utilized to characterize the similarities between the various compounds and to determine their interplanar spacings. The data were collected on a Rigaku D2000 at 298 K.

Magnetic susceptibility measurements were performed using a Quantum Design SQUID-based magnetometer utilizing modifications and procedures described elsewhere.⁷ Field-dependent, temperature-dependent, and remnant magnetization powder measurements were performed on the 4-phenylenediaminium (**1**), benzidinium ($H_3NC_6H_4C_6H_4NH_3$) (**2**), 4-fluororanolinium (**3**), 4-toluidinium (4-methylanilinium) (**4**), and 4-nitroanilinium (**5**) analogs. The data were corrected for diamagnetism (**1**: -140×10^{-6} emu/mol; **2**: -153×10^{-6} emu/mol; **3**: -166×10^{-6} emu/mol; **4**: -183×10^{-6} emu/mol; and **5**: -176×10^{-6} emu/mol) using Pascal's constants for the diamagnetic contributions⁸ and a TIP correction of 60×10^{-6} emu/mol per Cu(II) ion.

III. RESULTS AND DISCUSSION

A. Structure

The crystal structures of composites **1** and **5** are qualitatively similar to their p -alkyl counterparts,⁹ consisting of two-dimensional stacked arrays of corner-sharing $CuCl_6$ octahedra with the organic counterions acting as spacers between the layers. An example of one of the layers comprising the inorganic sublattice of compound **1** is illustrated in Fig. 1, which depicts the slight puckering of the tetrachlorocuprate layers.

Compound **1** possesses monoclinic symmetry and crystallizes in the $P2_1/c$ space group [$a=10.019(2)$ Å, $b=7.551(2)$ Å, $c=7.164(2)$ Å, and $\beta=93.17(2)^\circ$] while compound **5** possesses orthorhombic symmetry and crystallizes in the $Pbca$ space group [$a=7.065(2)$ Å, $b=32.494(8)$ Å, and $c=7.934(2)$ Å]. The presence of the nitro group in compound **5** effectively staggers successive layers in the a and c direc-

FIG. 1. Two-dimensional tetrachlorocuprate layer of compound 1.

FIG. 2. Powder XRD spectra of compounds 1–5. The spectra have been calibrated with Nb powder ($2\theta=38.47^\circ$) with appropriate d spacings shown (in Å).

tions, permitting only every other layer to be eclipsed as in $(\text{CH}_3\text{NH}_3)_2\text{CuCl}_4$,^{3b} giving rise to the highly anisotropic unit cell (the a axis of compound 1 corresponds to the b axis of compound 5). The ionic nature of the phenylenediaminium dication facilitates the smallest possible interlayer distance in the class of compounds under current investigation, with a d spacing of 10.0 Å (see Fig. 2). The bulkiness of the nitro and methyl substituents creates the largest d spacings of the compounds examined thus far, being 17.5 and 17.6 Å for analogs 4 and 5, respectively. The other related materials with differing para-substituents are being investigated at this time.

B. Magnetism

Figure 3 depicts the molar susceptibility (χ_m), inverse molar susceptibility (χ_m^{-1}), and magnetic moment (μ_{eff}) for compound 1 over the temperature range 5–20 K. The data were collected at an applied field of 10 Oe, with the line through the data being an aid to the eye only, and not a fit to any magnetic model. The resultant curve exhibits a divergence in susceptibility which can be seen to be similar to the low-temperature magnetic data of related tetrachlorocuprate composites.^{3b,c,10} The cusp in the molar susceptibility at 11.5 K is indicative of a magnetic phase transition. An important aspect of the molar susceptibility data is that the magnitude at the lowest measured temperature is approximately 67% of the magnitude at $T_C=11.5$ K. The curvature suggests that extrapolation to $T=0$ would have little effect on this ratio, implying that the critical temperature corresponds to the T_N of an LRO antiferromagnet. This conclusion is further supported by the eclipsed structure and short interplanar distance in this compound (see Table I), as has been noted in the antiferromagnetically ordering perovskite $(\text{H}_3\text{NCH}_2\text{CH}_2\text{NH}_3)\text{CuCl}_4$,^{10a} and by magnetization measurements performed on compound 1 (not shown) which show saturation above 5000 Oe, a relatively large saturation field for this class of materials. High-temperature ($kT/J>1.5$ —not shown) magnetic susceptibility data were collected at high field strengths (nominally 5000 Oe) and fit to the two-dimensional ferromagnetic Heisenberg model for $S=1/2$ put forth by Baker *et al.*,¹¹ where

TABLE I. Interplanar spacing and T_C values for compounds 1–5.

Compound	Interplanar spacing (Å)	T_C (K)
(p-phenylenediaminium)CuCl ₄ (1)	10.0	11.5
(benzidinium)CuCl ₄ (2)	15.0	9.5
(p-fluoroanilinium) ₂ CuCl ₄ (3)	15.8	9.3
(p-toluidinium) ₂ CuCl ₄ (4)	17.5	8.5
(p-nitroanilinium) ₂ CuCl ₄ (5)	17.6	6.8

$$\chi_m = \frac{Ng^2\beta^2 S(S+1)}{3kT} \left(1 + \sum_{n \geq 1} \frac{\alpha_n}{2^n n!} x^n \right) \quad (1)$$

with $x = J/kT$ and the other symbols have their usual meaning (see Ref. 11 for the expansion coefficients). All of the compounds exhibit ferromagnetic exchange, with J values similar in magnitude ($12\text{--}15\text{ cm}^{-1}$) to their alkyl counterparts.²

The low-temperature data ($kT/J < 1.5$ —not shown) for the investigated compounds was collected with an applied field of 10 Oe, with the exception of compound 3, which was subjected to a field of 1.75 Oe. All of the susceptibility curves displayed phase transitions, with the T_C values and corresponding interplanar spacings summarized in Table I. The observed trend is similar to the alkylammonium compounds, where the T_C is inversely related to the interplanar spacings. The first point to be made about this series is the similarity of the spacing between compounds 4 and 5 as compared to their significant T_C difference. This may be due to the staggering present in the *p*-nitroanilinium analog, leading to an ineffective interlayer exchange pathway. The other noticeable relationship is the similarity in the T_C values of composites 2 and 3. The effect that the counterionic spacers have upon the T_C values in these composites becomes quite clear. The diverging susceptibility values, however, can be suggestive of either a lattice-dimensionality crossover, or a possible Kosterlitz–Thouless¹² ordering. The latter has been utilized to explain the low-temperature behavior in related complexes^{2,3b} and is a definite possibility for this series. The behavior of compound 1, however, is more likely attributable to a long range ordering owing to the reasons previously discussed.

IV. CONCLUSIONS

Using anilinium derivatives as counterions to form tetrachlorocuprate perovskite composites is remarkably successful, resulting in regularly modifiable structures. The only structural anomaly noted is composite 5, owing to the nature of the nitro substituent. Perovskite compounds with similar anilinium substituents are currently being studied in order to study steric versus electrostatic effects on the proximity of the counterions. This series is currently being continued to include the other halogens as anilinium substituents, as well as aniline,^{5b} 4-aminobiphenyl, and 4,4'-diamino-*p*-terphenyl [$\text{H}_2\text{N}(\text{C}_6\text{H}_4)_3\text{NH}_2$]. The latter composite possibility to date, however, has not been able to be synthesized by conventional means. Single-crystal studies are also underway on the five present compounds in order to further understand the nature of the magnetic phase transitions.

NiBr₂·3H₂O, a lower dimensional antiferromagnet

G. C. DeFotis, J. R. Goodey, A. A. Narducci, and M. H. Welch
Chemistry Department, College of William and Mary, Williamsburg, Virginia 23187

The trihydrate of nickelous bromide, NiBr₂·3H₂O, is examined magnetically for the first time. A Curie-Weiss fit, $\chi_M = C/(T - \theta)$, to the susceptibility between 70 and 300 K yields $g = 2.31 \pm 0.01$ ($S = 1$) and $\theta = 6.6 \pm 0.5$ K. Systematic curvature in χ^{-1} vs T is evident below 70 K. Despite the positive θ , NiBr₂·3H₂O appears to order antiferromagnetically at $T_c = 3.82 \pm 0.05$ K, somewhat below a maximum in $\chi(T)$ at $T(\chi_{\max}) = 6.17 \pm 0.10$ K, with $\chi_{\max} = 0.0900 \pm 0.0005$ emu/mol. The ratio $T_c/T(\chi_{\max}) = 0.62 \pm 0.01$ suggests lower magnetic dimensionality. Between 4 and 12 K an acceptable fit with a two-dimensional Heisenberg model can be made, with $g = 2.58 \pm 0.01$, $J/k = -1.36 \pm 0.02$ K (assuming $\hat{H}_{\text{ex}} = -2J \sum_{i,j} \hat{S}_i \cdot \hat{S}_j$), and a correction for interlayer exchange $z'J'/k = -0.99 \pm 0.02$ K. Well above T_c the susceptibility is analyzed assuming axial and rhombic crystal field distortions, i.e., $D[\hat{S}_z^2 - S(S+1)/3]$ and $E[\hat{S}_x^2 - \hat{S}_y^2]$ spin Hamiltonian terms, with exchange included in a mean field approximation: $g = 2.33 \pm 0.02$, $D/k = 57.3 \pm 5.0$ K, $E/k = -24.9 \pm 3.0$ K, and $zJ/k = 5.28 \pm 0.20$ K. The parameters are provisional lacking single-crystal data, but the zero-field splitting is clearly quite large. Magnetization versus field isotherms depart only slightly from linearity for fields above 10 kG, and show a small hysteresis, even for temperatures above T_c . It is likely that ferromagnetically coupled NiBr₂NiBr₂Ni... chains are present, and that there are antiferromagnetic interactions between chains, such that strongly coupled layers occur, with weaker interactions between layers. © 1996 American Institute of Physics. [S0021-8979(96)50008-2]

I. INTRODUCTION

The magnetic properties of NiBr₂ and certain of its hydrates have been studied, though not nearly as extensively as those of the corresponding chloride salts. NiBr₂ orders antiferromagnetically near 60 K,¹ the available data being too imprecise for greater exactness. NiBr₂·2H₂O is presumed to order antiferromagnetically (only the heat capacity has been measured at low temperatures) at 6.23 K, with a likely spin reorientation transition occurring at 5.79 K.² Most of the magnetic entropy is removed above the 6.23 K transition, suggesting that the material is of low magnetic dimensionality. NiBr₂·6H₂O has been more thoroughly studied and shown to order antiferromagnetically at 8.30 K,³ rather than at 6.50 K as an earlier report had it.⁴ The magnetism is clearly three dimensional and there are several detailed similarities with the behavior in isomorphous NiCl₂·6H₂O.⁵ However, heat capacity data for NiCl₂·6H₂O provide evidence for lower dimensional character.⁶

NiCl₂·4H₂O is well studied,^{7,8} some indications of lower magnetic dimensionality being apparent. There is no known tetrahydrate of NiBr₂. Rather, for temperatures in the 36–60 °C range (where NiCl₂·4H₂O is obtained from aqueous solution of NiCl₂), NiBr₂·3H₂O is formed.⁹ Nor is there a reported trihydrate of NiCl₂. In this paper the magnetic properties of NiBr₂·3H₂O are examined.

II. EXPERIMENT

NiBr₂·3H₂O was prepared by evaporating an aqueous solution of NiBr₂ to dryness at 40 °C and maintaining the solid at 50 °C for 24 h. Fine-grained yellow-green polycrystalline material was obtained. Exposure to atmospheric water vapor in handling of the material was minimized. Thermogravimetric analysis confirmed that trihydrate was obtained. An x-ray powder diffraction pattern showed many similarities

with the known pattern of NiBr₂·2H₂O,¹⁰ but also significant differences. It seems likely that the structure of NiBr₂·3H₂O, as yet unknown, is related to that of the dihydrate. Magnetic measurements were made with a vibrating sample magnetometer system¹¹ using a 0.1865 g sample. Susceptibilities are corrected for diamagnetism ($\chi_{\text{dia}} = -123 \times 10^{-6}$ emu/mol) and demagnetization.

III. MEASUREMENTS AND ANALYSIS

Figure 1 shows χ_M^{-1} vs T for polycrystalline NiBr₂·3H₂O. A correction has also been applied for an assumed Van Vleck temperature-independent paramagnetic contribution of 240×10^{-6} emu/mol. This value follows from the expression¹² $\chi_{\text{VV}} = (N_0 \mu_B^2 / \lambda)(2 - g)$ assuming an effective spin-orbit coupling constant $\lambda = -270$ cm⁻¹, somewhat smaller and typically so for octahedral Ni²⁺ systems than the free ion value $\lambda = -315$ cm⁻¹, and a g value of 2.25, also typical for Ni²⁺ compounds. For temperatures above 70 K good linearity is apparent in the plot; below 70 K deviations occur, and are fairly pronounced below 50 K. A Curie-Weiss fit [$\chi_M = C/(T - \theta)$, with $C = N_0 g^2 \mu_B^2 S(S+1)/3k$ and $S = 1$] in the 70–300 K range yields the mean g value and Weiss θ given in Fig. 1. The g value of 2.31 is plausible for a Ni²⁺ system. The positive θ means that ferromagnetic interactions predominate, even though the overall behavior is antiferromagnetic.

Figure 2 shows the susceptibility in the low-temperature regime in more detail. A rounded maximum is evident, with $T(\chi_{\max}) = 6.17 \pm 0.10$ K and $\chi_{\max} = 0.0900 \pm 0.0005$ emu/mol. Below $T(\chi_{\max})$ a maximum in $\partial\chi/\partial T$, which it is plausible to identify with an antiferromagnetic transition,¹³ occurs at $T_c = 3.82 \pm 0.05$ K. Both the broadness of the maximum and the relatively low ratio $T_c/T(\chi_{\max}) = 0.62 \pm 0.01$ suggest that lower dimensional magnetic behavior is occurring. An up-

FIG. 1. Inverse molar magnetic susceptibility vs temperature for $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$ and Curie-Weiss fit.

turn in $\chi(T)$ sets in near 2.55 K. Since this feature is somewhat sharp it is questionable whether paramagnetic impurities are responsible. However, no known hydrate of NiBr_2 , or even NiCl_2 orders in this region.

Sufficiently above T_c , $\chi(T)$ for an ordering $S = 1$ system can be analyzed including the effects of axial and rhombic crystal field distortions, which produce a zero-field splitting of the 3A ground term. Including the Zeeman interaction the spin Hamiltonian is

$$\hat{H} = D[\hat{S}_z^2 - S(S+1)/3] + E[\hat{S}_x^2 - \hat{S}_y^2] + g\mu_B \mathbf{H} \cdot \hat{\mathbf{S}}. \quad (1)$$

Here g is assumed to be isotropic, as is often the case, or nearly so, in many Ni^{2+} systems. The eigenvalues in zero field correspond to three levels separated by $|D| - |E|$ and $2|E|$. Single-ion susceptibilities χ_x , χ_y , and χ_z can be calculated and the powder average susceptibility $(\chi_x + \chi_y + \chi_z)/3$ obtained,¹⁴ an expression parametric in g , D ,

FIG. 2. Molar susceptibility vs temperature below 16 K for $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$; curve through data is a theoretical fit described in text.

FIG. 3. Best fit to susceptibility data for $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$, with corresponding crystal-field and exchange parameters.

and E . The effects of exchange interaction, $\hat{H}_{\text{ex}} = -2J \sum_{i>j} \hat{\mathbf{S}}_i \cdot \hat{\mathbf{S}}_j$, must also be included, for which the mean field result is used,¹⁵

$$\chi^{\text{ex}} = \chi / [1 - (2zJ/Ng^2\mu_B^2)\chi], \quad (2)$$

where J is a mean exchange interaction over z neighbors.

A mean field approximation cannot be applied close to T_c and, therefore, fits to the data were done for $T \geq 12$ K. A rather good fit appears in Fig. 3, with a rms deviation of 1.1% between 12 and 300 K for the parameters indicated; unshown data above 60 K are very well accounted for. The g value is close to that emerging from the Curie-Weiss fit. The D and E parameters are exceptionally large, but acquire physical plausibility from the fact that deviations from Curie-Weiss behavior appear as high as 70 K and are marked below 50 K. This suggests that for such temperatures kT is comparable with energy separations in the ground multiplet: $|D|/k - |E|/k = 32.4$ K and $2|E|/k = 49.8$ K. The value of zJ/k is in good agreement, within 7%, with the observed Weiss θ according to the mean field relation $\theta = 2S(S+1)zJ/3k$. It should be noted that comparable quality fits could be obtained with negative D , e.g., $g = 2.31$, $D/k = -72.1$ K, $E/k = \pm 17.1$ K, and $zJ/k = 6.40$ K. Powder data do not permit an unambiguous determination of the sign of D ; moreover, all fits are insensitive to the sign of E . However, in all high quality fits D and E were large, and despite many attempts to model the data using much smaller D and E values the result was invariably a much poorer quality fit, especially for $T < 60$ K.

Given the lower dimensional characteristics in the data, already noted, attempts were made to fit $\chi(T)$ in the region between $\sim T_c$ and $\sim 4T_c$ with various lower dimensional models, using known high-temperature series expansions or exact results when available. Three-dimensional Heisenberg, XY, and Ising models were also tested and found inadequate, the observed susceptibility being more rounded in the vicinity of $T(\chi_{\text{max}})$ than the models permitted. A one-dimensional Heisenberg model yielded curves that were too broad for the observed susceptibility, as well as poor fits generally. Two-dimensional models clearly were capable of approximating

FIG. 4. Molar magnetization vs applied field at several temperatures for $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$; 4.220 K data are shifted up to 150 emu/mol for clarity.

the observed $\chi(T)$ more closely, and among these the 2D-Heisenberg model¹⁶ succeeded best. This is not unexpected since Ni^{2+} systems generally exhibit Heisenberg model behavior. A fit to the data between 4.2 and 12 K (data above 12 K are also shown) appears in Fig. 2. It is excellent, with rms deviation 0.82% for the parameters indicated. Interlayer exchange must be included, via a mean field approximation of the form of Eq. (2), in order to obtain an adequate fit.

Figure 4 shows the molar magnetization versus applied field at various temperatures. No transitions are apparent up to 16 kG, but there are deviations from linear behavior above 10–12 kG for each isotherm. The extent of these deviations is similar at each temperature. Moreover, there is some small hysteresis present for each isotherm (shown only in the case of 4.220 K for clarity), and its size is similar at each temperature.

IV. DISCUSSION

The magnetic behavior of $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$ is distinctly different from that of the related $\text{NiBr}_2 \cdot 2\text{H}_2\text{O}$ and $\text{NiBr}_2 \cdot 6\text{H}_2\text{O}$, although as noted earlier lower dimensional character is suggested by heat capacity data on $\text{NiBr}_2 \cdot 2\text{H}_2\text{O}$.² A remarkable feature of $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$ is the large size of the zero-field splitting parameters D and E . A structure determination could be very helpful in assessing the strength of distortions in the coordination sphere of the Ni^{2+} ions, which should be substantial in order to produce D and E parameters of the size determined here. In the case of $\text{NiBr}_2 \cdot 2\text{H}_2\text{O}$ a fit to heat capacity data yielded a provisional estimate $D/k = -10$ K.² A much smaller $D/k = -1.5$ K value was estimated for $\text{NiBr}_2 \cdot 6\text{H}_2\text{O}$.³ For the corresponding chloride materials, $\text{NiCl}_2 \cdot 2\text{H}_2\text{O}$ and $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, reported parameters are $D/k = 1.1$ and -1.5 K, respectively,^{17,5} with much smaller E values. For $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ a rather larger magnitude value $D/k = -11.5$ K has been reported,⁶ along with a small E .

While no clear trend is apparent it is likely that larger distortions occur in the Ni^{2+} environments of $\text{NiCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$. And certainly the location of the third water in relation to what must be a presumed $[\text{NiBr}_4(\text{OH}_2)_2]$ coordination sphere in $\text{NiBr}_2 \cdot 2\text{H}_2\text{O}$ is important in this respect. It should also be noted that for isostructural complexes larger zero-field splittings are frequently found for bromide than for chloride homologues,^{11,18} due to the greater covalency of the M-Br bond.¹⁹

There do remain certain puzzling features concerning the behavior of $\text{NiBr}_2 \cdot 3\text{H}_2\text{O}$, which probably cannot be fully resolved until a structure determination and single-crystal data are available. With very large zero-field splitting parameters and a moderate size exchange interaction it might be expected that ordering would not occur at finite temperature, according to theories which treat the effects of anisotropy and exchange on T_c ,^{20,21} and with large separations between the states of the ground triplet the success of an $S=1$ model in describing the low-temperature behavior is unexpected. As to the distribution of exchange interactions, it is most probable that ferromagnetically coupled $\text{NiBr}_2\text{NiBr}_2\text{Ni} \cdots$ chains occur, that for structural reasons these are coupled together antiferromagnetically into layers, and that antiferromagnetic interactions also occur between the layers. This accounts for the general results of the fittings.

The change in the interface profile between immiscible nonmagnetic liquids was investigated quantitatively in a superconducting magnet with a large horizontal bore. The interface profile changed into concave down or up at the field center accordingly to the balance of magnetic susceptibilities between the lower and upper liquids. A flat interface was also demonstrated when the susceptibilities were balanced. It was found that modification of the interface profile was significantly amplified under an applied field as low as 1 T when the densities of the two liquids were quite close. The morphological change induced by the applied magnetic field can be used to remove a boundary, which initially separates two liquids without the field, and to initiate a mixing process or a chemical reaction between the two liquids. © 1996 American Institute of Physics. [S0021-8979(96)50108-9]

Exploration of magnetism has been extended to nonmagnetic, i.e., dia- or paramagnetic, materials and living bodies since recent developments of superconducting magnet technology make it easier to access a high magnetic field. Indeed, it was observed that the surface of water bended downward under the field of 10 T or so at the center.^{1,2} We have demonstrated that this phenomenon, which we called as Moses effect, is attributed to the diamagnetism of water. We then showed that the surface profile of aqueous solutions was systematically modified accordingly as their magnetic susceptibility varied from diamagnetic to paramagnetic values. However, the applied field should be high and steep enough in order to clearly observe these effects.

In this work, we employed more than two immiscible liquids to observe the field effect on the interface. We show that the interface profile is governed by susceptibility values of two liquids contiguous at the interface. The morphological changes may be clearly observed under a field even weaker than 1 T when the densities of the two liquids are adjusted quite close.

The magnet used in this study had a large horizontal open bore 200 mm in diameter and 1300 mm in length, and could produce magnetic field directed along the bore (x) axis. A narrow glass vessel of 10 mm width was fixed in the magnet, and the whole profile of the liquids inside the vessel could be monitored from outside by using a pair of mirrors, which could slide along the x direction.

Table I summarizes the sample liquids. The density ρ of each copper sulfate (CuSO_4) aqueous solution was determined by weight and volume measurements, and its magnetic susceptibility χ was estimated from the measured weight of its source materials ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and H_2O) as

well as their specific susceptibilities listed in the literature.³ All the measurements were performed at room temperature.

Figure 1 shows a typical interface profile between two immiscible nonmagnetic liquids under various magnetic fields. The direction of the interface change, concave up or down, was dependent upon the specific combination of the sample liquids.

In Fig. 1(a), the lower liquid was sample A copper sulfate solution (blue), and the upper liquid was hexane (transparent). Here, hexane was added in sample A from the right side of the vessel under applied field of 8 T. The interface between sample A and hexane was flat, while the surface of sample A fell at the field center, and that of hexane moved up toward the right end of the vessel.

Figure 1(b) shows an interface between hexane (upper) and sample B (lower). Under the field of 3.8 T, the top surface of hexane fell by 9 mm, while the interface was raised by 24 mm. In Fig. 1(c) the upper liquid was substituted for

FIG. 1. Profile of the interface between an organic solvent (upper) and a copper sulfate aqueous solution (lower). The magnetic field was directed along the horizontal (x) axis. The sample liquids and the field strength at the center were (a) hexane and the solution A, 8 T; (b) hexane and the solution B, 3.8 T; (c) monochlorobenzene and the solution B, 0.9 T. The whole figure is a patchwork of 27–30 sectional photographs of which boundaries are seen as vertical shadows. The x direction is rescaled to $\frac{1}{4}$.

monochlorobenzene. When the field was reduced at 0.9 T, the interface was raised by 20.6 mm, though the top surface was almost flat.

It was also observed that the interface fell at the field center, as will be shown later in Fig. 2. Therefore, the interface profile may rise, fall, or be flat, depending on the combination of sample liquids. In addition, the interface profile can be enhanced: in Figs. 1(b) and 1(c), the height differences between the vertical interface level at the field center

and that at the two ends of the vessel were both about 20 mm, being comparable to that of the water surface under 8 T.

Next, we show that the observed profiles are quantitatively explained by taking the magnetic volume energy into account.^{2,4} The surface height y_2 is expressed as

$$y_2(x) = \frac{\chi_2}{\rho_2} \frac{(\mu_0 H(x))^2}{2g\mu_0}, \quad (1)$$

FIG. 2. Profile of the stack of three nonmagnetic liquids: hexane (upper), copper sulfate aqueous solution C (middle), and carbontetrachloride (lower). The applied magnetic field was 8 T at the center. The x direction is rescaled to $\frac{1}{4}$.

where the subscript 2 denotes the upper liquid, μ_0 the permeability in vacuum, and g the acceleration of the gravity. Equation (1) indicates that the surface height is proportional to $(\mu_0 H)^2$, and that the surface moves up or down at the field center, depending on the sign of χ_2 .

The proportional coefficient $k(=\chi_2/2g\mu_0\rho_2)$ was evaluated to be $0.78 k_w$, $1.20 k_w$, and $0.86 k_w$, for sample A, hexane, and monochlorobenzene, respectively, where $k_w = -3.66 \times 10^{-4} \text{ m/T}^2$ is the coefficient for water.² These values of k , being close to the value of water k_w , were why the height differences of their surfaces were comparable to that of water surface achieved under the same applied field.

In contrast, the interface height y_1 should be expressed as

$$y_1(x) = \frac{\chi_1 - \chi_2}{\rho_1 - \rho_2} \frac{(\mu_0 H(x))^2}{2g\mu_0}, \quad (2)$$

where the subscript 1 denotes the lower liquid.⁵ Equation (2) indicates that the interface height is also proportional to $(\mu_0 H)^2$, and that the direction of the interface change depends on the balance of susceptibilities between the two liquids, $\Delta\chi = \chi_1 - \chi_2$, because $\Delta\rho = \rho_1 - \rho_2 > 0$. When the susceptibilities are balanced, the interface is kept flat as shown in Fig. 1(a); when $\chi_1 > \chi_2$, the lower liquid rises, as shown in Figs. 1(b) and 1(c).

The proportional coefficient k may be enhanced in its magnitude by setting $|\Delta\chi|$ larger and/or $\Delta\rho$ smaller. The coefficient for Fig. 1(b) was evaluated to be $k = 3.6 |k_w|$, where both the values $|\Delta\chi|$ and $1/\Delta\rho$ were nearly twice the values $|\chi|$ and $1/\rho$ for water, respectively.

In particular, the enhancement is efficient when the densities of the two liquids are adjusted quite close: in Fig. 1(c), $\Delta\rho$ was set to be $\leq 0.023 \text{ g/cm}^3$, resulting in the coefficient $k = 82 |k_w|$. This is why we could observe the rise of interface as large as 20.6 mm even when the magnetic field was further reduced to 0.9 T.

Hence, Moses (fall) and reversed Moses (rise) effects can be significantly enhanced by designing an appropriate combination of sample liquids. We therefore call these significantly enhanced effects either an "enhanced Moses effect" or an "enhanced reversed Moses effect" depending on whether $\chi_2 > \chi_1$ or $\chi_2 < \chi_1$, respectively.

Nevertheless, be reminded that when $\Delta\rho$ becomes smaller the interfacial tension may compete with the enhanced Moses effect, and the interface profile may be modified. An example is seen in Fig. 1(c) as the irregular humps in the interface profile where the inner surface of the vessel once wet with one of the liquids hindered the further motion of the interface. A theoretical treatment of the enhanced Moses effect including the interfacial tension will be discussed elsewhere.⁵

Finally, we point out that morphological changes induced by the applied field may remove a boundary which initially separates two phases without the field.

Figure 2 shows interface and surface profiles of a stack of three nonmagnetic liquids: hexane, sample C copper sulfate aqueous solution, and carbontetrachloride. When the field was applied, the lower interface fell at the field center. Then, sample C deformed into a droplet, and floated on the bottom liquid, carbontetrachloride. At the same time, the upper liquid moved apart from the center. As a result, the top and bottom liquids were joined at the both ends of the vessel, gradually mixing into each other. Besides, the middle liquid, initially surrounded by the two liquids, was exposed at its top surface to air.

We consider that such kinds of morphological changes induced by an applied field can be used to initiate and terminate a mixing process or a chemical reaction between two liquids or between a liquid and the covering atmosphere.

Ferromagnetic–insulator–ferromagnetic tunneling: Spin-dependent tunneling and large magnetoresistance in trilayer junctions (invited)

Jagadeesh S. Moodera and Lisa R. Kinder

Francis Bitter Magnet Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Tunneling between ferromagnet–insulator–ferromagnet (FM–I–FM) trilayer thin-film planar junctions has been successfully studied. Tunnel current was observed to be dependent on the relative orientation of the magnetization (M). Co, CoCr, CoFe, Fe_{0.7}Pt_{0.3}, and NiFe were tried as the FM electrodes with Al₂O₃ or MgO as the barrier layers for the above studies. Large magnetoresistance (MR) was observed as the M alignment of the two ferromagnets changed from being parallel to antiparallel orientation. At room temperature, the highest change in junction MR was 18%, field sensitivity factor reaching 5%/Oe in the best cases. The MR value increased to 25.6% at 4.2 K, and decreased as the dc bias was increased to a fraction of the barrier height. The angular dependence of MR varied nearly as the cosine of the relative angle of M , as predicted by Slonczewski's theory. The magnitude of MR agrees well with that given by Julliere's model, which predicts that the MR varies as the product of the conduction electron spin polarization of the FMs. These trilayer junctions can find application as high-density, nonvolatile storage media or as field sensors.

INTRODUCTION

Spin-polarized tunneling experiments between a superconductor and a ferromagnet, performed 25 years ago,^{1,2} led the way to the present field-dependent tunneling between FM films. Based on the earlier spin-polarized tunneling results, Julliere put forward a model for FM–I–FM tunneling,³ assuming that spin is conserved in tunneling² and tunnel current is dependent on the density of states of the two electrodes. Due to the uneven spin distribution of conduction electrons at the Fermi level in the FMs, one can expect tunneling probability to be dependent on the relative magnetization orientation of the FM films. Analyzing the tunnel current, based on the spin density of states at the Fermi level of the two FM electrodes, Julliere showed the change in the tunnel conductance (ΔG) between antiparallel and parallel orientation of the two FMs as

$$\Delta G/G = 2P_1P_2/(1 + P_1P_2), \quad (1)$$

where G is the conductance when the magnetizations are parallel, and P_1 and P_2 are the spin polarizations of the two FM electrodes. The change in the tunnel resistance can be written as

$$\Delta R/R = (R_A - R_P)/R_A = 2P_1P_2/(1 + P_1P_2), \quad (2)$$

where R_A and R_P represent the junction resistances when the two FMs have their M antiparallel and parallel, respectively. This latter definition is used in deducing the MR throughout the present work.

Another theory of FM–I–FM tunneling proposed by Slonczewski analyzes the transmission of charge and spin currents through a rectangular barrier separating free-electron-like FM metals.⁴ The orientation of the spins tunnel-

ing across the FM–I interface was strongly influenced by the barrier height, according to this theory. This affected the spin polarization and the exchange coupling between the FMs and was consistent with the low values of $\Delta R/R$ seen previously.^{5–11}

The experimental values have come far short of the expected value according to Julliere's model, until very recently. For instance, in the case of Fe–I–Co tunnel junctions, with $P=40\%$ and $P=34\%$, respectively,^{1,2} the expected junction MR should be 24%. Julliere studied Fe–Ge–Fe and Fe–Ge–Co junctions and obtained a change of 14% in the conductance at 4.2 K and zero bias.³ This percentage dropped to less than 1% upon the application of several mV of dc bias to the junction. Various other groups, using mainly NiO, CoO, Gd₂O₃, and Al₂O₃ barriers, studied this effect and only small changes were seen—no more than 7% at 4.2 K.^{5–11} In recent times, Miyazaki and his co-workers have improved the room-temperature results from 2.7% to 15.6% [according to the above definition, Eq. (2)].¹² However, the 15.6% value was seen in only one junction and was not reproducible. Using low-temperature deposition techniques, it was recently shown that reproducible results can be obtained using Al₂O₃ barriers with the highest change being 12% for CoFe/Al₂O₃/Co tunnel junctions at room temperature.¹³

Many limiting factors can reduce the MR effect: orange peel coupling between the FMs due to surface roughness,¹⁴ interfacial and barrier spin scattering, FM surface degradation, domain walls, etc. By significantly overcoming some of these negative factors in the present work, values of $\Delta R/R$ have greatly improved to as high as 18% at room temperature and 25.6% at 4.2 K for CoFe/I/Co junctions. This is

close to the expected value of 27.6% predicted by Julliere's model. In the present work, a sensitivity factor of 5%/Oe is obtained for the tunnel junction devices.

EXPERIMENT

The thin-film planar junctions used for MR measurements were fabricated *in situ* through vacuum evaporation, in a system with a background pressure of 10^{-7} Torr. Glass substrates cooled to 77 K were covered with 1 nm thick Si (which serves as a nucleating layer beneath the first electrode). Then, the first FM base electrode, 8.0–15.0 nm thick and 0.2 mm wide, was deposited without or with an applied magnetic field (H) to align with an easy axis of magnetization. The base electrode deposition was followed by the evaporation of 1.2–2.0 nm of Al or Mg metal, covering the *entire* base electrode, to form the tunnel barrier.¹⁵ The substrates were then warmed to room temperature and subjected to oxygen glow discharge to create an insulating layer of Al_2O_3 or MgO . Finally, the top FM electrode, 8.0–25.0 nm thick and 0.3 mm wide, was deposited. The FM materials used include Co, CoCr, CoFe, $\text{Fe}_{0.7}\text{Pt}_{0.3}$, and NiFe. The thickness was monitored by a quartz-crystal oscillator. In each run, a total of 72 junctions, each with an area of $6 \times 10^{-4} \text{ cm}^2$, were prepared. The junction resistance (R_J) ranged from hundreds of ohms to tens of kilohms.

Junction MR was measured using a four-terminal ac or dc technique in fields up to $\pm 0.5 \text{ T}$, in the temperature range of 4.2–325 K. For ac measurements, a Linear Research-400 ac resistance bridge with an accuracy of $\pm 0.005\%$ was used and dc measurements also had similar accuracy. Measurements were done with H parallel or perpendicular to the junction plane. Several junctions were subjected to higher dc voltages to elucidate the bias dependence of the junction properties. These measurements were taken with voltages ranging from 0 to 0.8 V at 4.2, 77, and 295 K. Detailed temperature dependence of R_J , $\Delta R/R$, and tunnel current was measured between 4.2 and 295 K for some junctions. To control the temperature, the junctions were mounted on a sample probe with a heater. A platinum resistance thermometer, mounted adjacent to the sample, monitored the temperature. Angular dependence was measured at room temperature with the junction plane parallel to the field. R_J was recorded as the sample was rotated from 0° to 360° .

RESULTS

Several criteria were used to qualify the junctions for magnetotransport studies. As a first requirement, junctions with a resistance in the range of 1 k Ω to tens of kilohms were chosen for measurements. To prove that tunneling is the main source of conductance, $G(V)$ and $I(V)$ characteristics were taken for several junctions. Figure 1 shows the conductance of a $\text{CoFe}/\text{Al}_2\text{O}_3/\text{Co}$ junction as a function of both low and high voltages at 4.2 K. At low bias, the conductance is nearly constant. However, at high bias nearly a parabolic dependence is observed. This behavior is expected for a good tunnel junction with a barrier height of above $\sim 1 \text{ eV}$. At 4.2 K, a conductance dip was generally seen at zero bias,

FIG. 1. Tunnel conductance as a function of dc bias for a $\text{CoFe}/\text{Al}_2\text{O}_3/\text{Co}$ junction at 4.2 K. The lower curve was taken in the lower bias region and the upper curve is for the higher bias. The voltage scale for the lower curve should be divided by 500. For the higher bias region, data at 295 K are also shown.

whereas at 77 K and room temperature, the conductance dip was negligible. This feature will be discussed later.

$I-V$ curves taken from 0 to 0.8 V also confirm the quality of the junctions. At low bias, ohmic behavior was seen and higher bias showed parabolic dependence. Simmons's theory of tunneling was used to derive the barrier height (ϕ) and thickness (s) for several junctions.¹⁶ For Al_2O_3 barriers, ϕ ranged from 1.8 to 3.5 eV. The corresponding barrier thicknesses varied from 1.8 to 1.2 nm. For the limited studies done with MgO barriers, values of $\phi \approx 0.9 \text{ eV}$ and $s \approx 2.1 \text{ nm}$

FIG. 2. Magnetoresistance of the tunnel junction and the two FM film electrodes as a function of applied magnetic field, taken at room temperature. The arrows indicate the direction of M in the two FMs, according to the FM-I-FM model of Julliere. (See Discussion).

FIG. 3. Junction magnetoresistance vs applied magnetic field showing the variation in the higher field range for CoFe/Al₂O₃/Co and Fe_{0.7}Pt_{0.3}/Al₂O₃/NiFe samples. Note the field independence of MR at fields slightly beyond the peak.

were obtained. These barrier parameters are what is typically seen for standard Al₂O₃ and MgO tunnel barriers.

Good tunnel junctions with the above barrier parameters showed mostly a small temperature dependence of R_J . The junctions used in the present studies showed only a 10% to 30% increase in R_J as temperature was decreased from room temperature to 4.2 K. According to Simmons's and Stratton's tunneling theory, the tunnel current varies linearly with $T^{2.17}$. This behavior was observed in the present junctions at temperatures <60 K. Also, these junctions withstood temperature cycling, high voltages (up to ± 0.8 V), and were stable in the ambient conditions.

MR measurements, displayed in Figs. 2 and 3, show a change in R_J as a function of applied field (H). At high field, the junction resistance is low, and it begins to increase as H decreases toward zero field. Upon reversing the field direction, R_J rapidly rises, showing a peak. With further increase in H , R_J drops to its original low value. The ratio of the peak change to the absolute value at the peak is defined as $\Delta R/R$. (This definition gives a lower value of the ratio as compared to the criteria used by others where the resistance change was divided by the low value of R_J at high H). In Fig. 2, the CoFe/Al₂O₃/Co junction shows a $\Delta R/R$ of 10.6% at 300 K. Compared to the junction, the MR of the FM electrodes is also shown. The changes in the resistance for the full length of the strips are about 0.6% and 0.1% for Co and CoFe films, respectively. The junction area corresponds to only 1/30th of the length of the electrodes. In essence, the MR contribution of the FM film is negligible. Figure 3 shows the R_J vs H in the higher field range for two junctions at room temperature. The constancy of R_J as H increased beyond the peak value is evident.

MR effects were investigated with different FM electrodes like Co, CoCr, CoFe, Fe_{0.7}Pt_{0.3}, and NiFe and barriers of Al₂O₃ or MgO. Keeping CoFe as one electrode showed the highest percentage change. The maximum change was 25.6% at 4.2 K and 18% at room temperature for the CoFe/Al₂O₃/Co trilayer. Many junctions consistently showed changes in the range of 14%–17% at room temperature. The

FIG. 4. Angular dependence of the junction magnetoresistance taken at low and high applied fields for a CoFe/Al₂O₃/Co junction.

peak position at room temperature for various junctions occurred between 3 and 120 Oe. For example, CoFe/Al₂O₃/Co and CoFe/Al₂O₃/NiFe junctions deposited in the absence of H showed the peak at ± 120 Oe, whereas the peak for junctions prepared in an applied field occurred at ± 3 Oe. The peaks occurred at lower field values for thicker NiFe films and for films that were deposited in the presence of an applied field. The peak position and height did not change with field cycling. Also, upon reaching the maximum of R_J , when the field was turned off, the peak value of the resistance was maintained at $H=0$.

The angular dependence of MR was measured for several junctions, for a low and a high value of H , keeping H in the film plane. In order to perform this measurement, the junctions were subjected to a high field in the junction plane in one direction. Upon reversing the field, a low value of H was set (less than the peak field value). R_J was then recorded every 5°–10° as the sample was rotated with respect to the field. Seen in Fig. 4 is the periodic variation of R_J as a function of angle, showing cosine of the angle dependence (not shown in the figure) as discussed in Slonczewski's theory.⁴ When similar measurements were done at a field value higher than the peak field, R_J remained constant (the lower curve in the figure). The maximum change in R_J (for low field) with respect to the angle nearly correlated with the $\Delta R/R$ observed in R vs H measurements.

In general, the MR of the junctions increased as the temperature was lowered. For example, in some cases, $\Delta R/R$

FIG. 5. The dc bias dependence of junction MR for a CoFe/Al₂O₃/Co junction at 4.2, 77, and 295 K.

nearly doubled as the sample was cooled from room temperature to 77 K, and continued to increase as T decreased to 4.2 K. However, in certain cases, the $\Delta R/R$ slightly decreased upon cooling. This will be discussed later. Some junctions were warmed to 325 K and found to be stable. However, the $\Delta R/R$ value slightly decreased at higher temperatures.

The magnetoresistance dependence on the dc bias is displayed in Fig. 5 for a CoFe/Al₂O₃/Co junction. As the dc bias increased, the $\Delta R/R$ increased slightly or remained constant at low bias. At higher voltages, the $\Delta R/R$ declined rapidly, reaching lower MR values. It is important to note that up to a few tens of mV, the decrease is not significant. Junctions with MgO barriers also displayed similar bias dependence of MR. Thicker Al junctions showed lower MR and the visible presence of unoxidized Al. The larger change in the R_J as a function of temperature and considerable asymmetry in the $G(V)$ curve indicated that for thinner barriers (below 1.4 nm), the base electrode was partially oxidized.

DISCUSSION

The junction magnetoresistance can be understood based on Julliere's model.³ Referring to Fig. 2, at high fields, the two FM films have their M aligned in the applied H direction. (The M direction is indicated by arrows.) Upon reversing the field, the magnetization of the film with a lower coercive force (H_C) aligns itself in the new field direction. On the other hand, the second electrode, with a higher H_C , re-

mains magnetized in the original field direction. In this configuration, the magnetization of the two films are antiparallel to each other. As the field is increased further, it becomes strong enough to align the M of the second FM electrode in the new field direction, resulting in parallel orientation. Thus, at high fields in either direction, the FM electrodes are saturated and parallel to each other. At intermediate fields, the electrodes are aligned antiparallel. According to the model presented in the introduction, when M are parallel, the tunneling probability is highest and tunneling current is maximum, thereby yielding a low R_J . In the antiparallel configuration, the tunneling probability and the current are lowest, resulting in higher R_J .

The MR curves of the two electrodes (see Fig. 2) clearly support the above interpretation. For instance, the extrema points of these curves indicate the coercive forces of the electrodes.¹⁸ The peak in R_J is centered between the lower H_C of Co and the higher H_C of the CoFe film. Thus the peak position of the junction resistance is strongly correlated to the coercive fields of the FM electrodes. The H_C of the FM film is easily influenced by the film growth conditions: the presence of an applied magnetic field during film growth, substrate temperature, a nucleating layer, thickness of the film, etc.¹⁹ CoFe/Al₂O₃/(NiFe or Co) junctions with the films deposited in the presence of an applied field showed a behavior different from those discussed above. For instance, the peak in R_J occurred at 3 Oe as compared to the peak in CoFe/Al₂O₃/(NiFe or Co) junctions, deposited in $H=0$, which occurred at about 120 Oe. Also, the peaks were extremely sharp, with a peak width of less than 3 Oe as compared to over 100 Oe in the other case. The sharpness and low H value of the peak position are directly the result of film growth in the presence of field, which reduces the H_C of the FM film and makes it sharper.¹⁹ Thus, among many other factors, the sharpness and position of the H_C of two FM electrodes strongly influences the MR of the junction.

As pointed out in the previous section, the MR remained constant all the way to 0.5 T, beyond 2 or 3 times the peak value of the applied field (Fig. 3). During the oxidation of Al to form the Al₂O₃ barrier, it is possible that the top surface of the base electrode is partially oxidized as well, creating perhaps an antiferromagnetic (AF) oxide layer like CoO or FeO. In such a situation, one ends up with an FM/AF interface which can exhibit exchange anisotropy, perhaps detrimentally influencing the polarization of the electrons at the interfaces. The presence or absence of exchange anisotropy can be inferred by the shape of R_J vs H at high fields²⁰ and also by the displaced $M-H$ loop. As seen in Fig. 3, the near absence of MR at fields beyond ~ 0.05 T, and the symmetric $M-H$ loop observed point to the absence of exchange anisotropy caused by an AF oxide. The data in Fig. 3 were taken at room temperature. However, at 4.2 K, R_J vs H was slightly asymmetric, showing some MR effects even beyond 0.15 T. The $M-H$ loop was also asymmetric at 4.2 K showing the possible presence of an AF layer over the FM.¹⁴

The rotation of the magnetization of one FM with respect to the other also supports the FM-I-FM tunneling model. This is evident in the data shown for a CoFe/Al₂O₃/Co junction in Fig. 4. At a field value higher

than the H_C of one electrode, when the sample is rotated in a magnetic field, the M of the softer film follows the field. This will change the relative orientation of M in the two FM films—switching from parallel to antiparallel orientation gradually. The tunneling probability is therefore affected, which is evidenced by the periodic variation of the R_J with the angle, as seen in this figure. The maximum value of the resistance corresponds to the antiparallel alignment of the relative magnetizations. The parallel orientation of M goes with the minimum of the curve. At field values higher than the H_C of both electrodes, if the above interpretation is correct, rotation of the sample in the field should maintain the parallel orientation of M (along the applied field) at all angles of H . In this case, the tunneling probability should be the highest and R_J should maintain a constant low value. This is exactly what is seen in the second curve which was taken at high field. Thus the angular dependence and the field dependence of R_J conclusively support the FM–FM tunneling model. The exact form of angular dependence of MR was not quite the cosine function predicted in Slonczewski's theory for the tunnel conductance.⁴ The likely distribution of the H_C in the present FM films can contribute to this behavior.

The magnetoresistance behavior of the junction with applied magnetic field in the film plane and perpendicular to it was similar. In perpendicular field, the peaks were relatively broader and occurred at slightly higher field values. The latter peaks were several times broader than the peaks with H in the plane, if the films were deposited in a magnetic field parallel to the substrate plane. However, the MR of the junction remained the same. M – H measurements showed that CoFe and Co films have their M in the film plane. So, when the field is perpendicular to the film plane, the film has to rotate toward the hard axis, thereby shifting the peaks to higher field values and also making them broader; the shift becomes even larger when the films are deposited in an applied magnetic field. Despite these variations, the tunneling model as discussed above is operative here, i.e., even when the magnetizations are perpendicular to the film plane.

Magnetoresistance, junction resistance, tunnel current, and peak position all varied with temperature. As the temperature decreased from 300 to 4.2 K, the MR nearly always increased. The H_C of the elemental FM increased more than that of the alloy FM as the temperature decreased. This allowed broader separation of H_C for the two FMs in some cases, if they were near each other at RT, creating a better antiparallel alignment (wider peaks). Also, at lower temperatures the M – H loop of the FM films got sharper, with a higher value of H_C and remanent magnetization. This can give rise to larger MR effects and peaks shifting to higher H as T decreased. Room-temperature values for $\Delta R/R$ varied between 10% and 18% whereas at 4.2 K, the values went up to 21%–26%. Exceptions to the increase in $\Delta R/R$ with decreasing temperature occurred when the coercive fields of the two films changed such that they moved toward each other with decreasing temperature, creating a sharper peak and bringing down the MR effect. For instance, in the case of certain CoFe/Al₂O₃/NiFe junctions where the FM films were deposited in the presence of H , the H_C were so close to each

other that the width of the peak was less than 3 Oe.

The R_J increased with a decrease in the temperature in all cases, the thinner barriers showing a higher percentage change. This is not unexpected since a thinner Al film barrier would allow possible oxidation of the base electrode, thus forming a temperature-dependent, semiconducting barrier at the interface. Such strongly paramagnetic oxide in the interface region can create spin scattering at RT, whereas at lower temperatures, magnetic ordering of this layer would reduce the spin scattering. If this is the case, MR can increase as temperature decreased.

The MR shows surprisingly strong decrease as the bias increased from 0 to 0.8 V. There was no change in $\Delta R/R$ for ac bias up to 1 mV. With dc bias, although $\Delta R/R$ initially showed a small increase or near constant value below ~ 10 mV at RT, overall it decreased with increasing dc bias. The decrease was small up to about 100 mV, and beyond which, it decreased faster. The value of $\Delta R/R$ at 0.8 V was about 1/5 of the low bias value; MgO barriers showed more decrease as compared to Al₂O₃ barriers. Also, if the $\Delta R/R$ at $V=0$ was lower, then the decrease with bias was larger. Irrespective of the starting $\Delta R/R$, the relative change was similar at 300, 77, and 4.2 K. Many causes can contribute to the decrease in the MR with bias. Among them, the bias dependence of the barrier height, creation of magnons, density of states effects in the FM, etc., may be responsible for the decrease in $\Delta R/R$. With the increase in dc bias, the effective barrier height decreases. MgO, with its smaller barrier height, is affected more than the Al₂O₃ barrier. This can increase the tunneling probability for the minority spins. The spin polarization of the tunneling current can then be expected to decrease, as discussed in Slonczewski's theory.⁴ This might also explain strong bias dependence of the effect seen in Julliere's experiment.³ The α -Ge (although exposed to oxygen) tunnel barrier which Julliere used is known to have a barrier height of 20–30 meV.²¹ In this experiment, MR effects were only seen at helium temperatures below about 10 mV. This is the general trend that has been observed with other low barriers like NiO, Gd₂O₃, CoO, etc., where the junction MR effects were seen only at low temperatures and smaller bias.^{5–11}

The presence of metal particles,²² magnons,²³ magnetic impurities, localization effects, multistep tunneling, and states in the barrier or at the interface can adversely affect the spin polarizations of the tunneling electrons by causing spin flip scattering.²⁴ The dip in the conductance at $V=0$ observed at 4.2 K can be due to some combination of the above causes. One would expect by the presence of metal particles in the tunnel barrier (for example, unoxidized Al left in the barrier) a characteristic $G(0)$ vs T dependence below 4.2 K.²² No measurable temperature dependence of $G(0)$ was observed between 1 and 4.2 K. However, if the metal particles are less than a few Å, then no significant temperature dependence can be expected.²² In addition to a conductance dip, small features were observed in G vs V curves around 100 mV, especially in junctions with thinner barriers. This is consistent with the magnon formation as has been found in NiO by Tsui *et al.*,²³ causing spin flip during tunneling. Also, that the anomaly in G at $V=0$ is not the

cause of the MR is evident from the near independence of G vs V and large MR at room temperature, and only a small decrease in the effect at low bias (below ~ 100 mV), even at low temperatures.

The conduction electron spin polarization values that are used here were measured at the Fermi level. At high bias, one deals with the states away from the Fermi level which need not have the same spin polarization. If such is the case, then at higher bias, the effect ($\Delta R/R$) might decrease if the polarization is lower away from the Fermi level. Spin-polarization measurements at energies higher than at the Fermi level would be helpful. The magnitude of the MR effect can be calculated, for example, for CoFe/Al₂O₃/Co junctions according to Julliere's model [Eq. (2)]. The conduction electron spin polarization of 47% for CoFe was measured at 0.4 K using the spin-polarized tunneling technique as described in Refs. 1 and 2. Using a value of 34% for Co polarization,² one gets a calculated change of 27.6%, from Eq. (2). This compared well with the MR seen in the present junctions at 4.2 K.

CONCLUSIONS

Large magnetoresistance was observed in the FM-I-FM tunnel junctions (where FM=Co, CoCr, CoFe, FePt or NiFe, and I=MgO or Al₂O₃). This effect increased at lower temperatures. A significant decrease in MR was observed with increasing dc bias. At room temperature, MR values of 14%–17% were consistently obtained. The highest value of 18% was seen in CoFe/Al₂O₃/Co junctions. This value increased to 25.6% at 4.2 K which agrees well with the value of the MR estimated from the conduction electron spin polarization of the FMs, using Julliere's model. These trilayer devices and MR effects have potential as ultralow power field sensors or memory elements due to the small size, high R_J , independence of FM, barrier layer thickness, and field orientation.

Theory of spin-dependent tunneling and transport in magnetic nanostructures (invited)

S. Maekawa, J. Inoue, and H. Itoh

Department of Applied Physics, Nagoya University, Nagoya 464-01, Japan

We study the linear response theory of the electric transport in magnetic nanostructures. The conductance is expressed by using the wave functions of electrons on the Fermi level in the mean field theory at zero temperature. The theory is extended to the system with single resistive layer in which there exists electron–electron interaction and the conductance is derived in the single-site approximation. The theoretical results may be applied to a variety of magnetic nanostructures such as magnetic multilayers and ferromagnetic tunneling junctions. © 1996 American Institute of Physics. I. INTRODUCTION

Spin-dependent transport phenomena have received much attention since the discovery of the giant magnetoresistance (GMR) in magnetic multilayers.¹ GMR was also observed in granular alloys.^{2,3} In addition, there is growing interest in the study of magnetoresistance devices of magnetic nanostructures. These activities renewed the study of ferromagnetic metal/insulator/ferromagnetic metal tunneling junctions which were the first of the observation of magnetoresistance in the magnetic nanostructures.^{4,5} The magnetoresistance in the tunneling junctions is called the tunneling magnetoresistance (TMR). Recent experiments have shown that TMR is as large as GMR in magnetic multilayers.^{6,7} We note that TMR is also seen in magnetic granular semiconductors.^{8,9}

Although interesting magnetoresistance phenomena have been observed in magnetic nanostructures, the theoretical study is far from complete. This is partly because it is not easy to take into account the nanostructure and random scattering potentials on an equal footing.

In this article, we formulate the conductance in magnetic nanostructures. Starting with the Kubo formula for the conductance, we find that the conductance depends only on the voltage at leads attached to the sample and does not depend on the detailed electric field distribution in it in the mean field theory at zero temperature, indicating that the theory for the nonlocal conductivity by Kane, Serota, and Lee¹⁰ is valid in the magnetic systems as well. We extend this result and examine the transport in a system with single resistive layer in which there exists electron–electron interaction. In the single-site coherent potential approximation (CPA), we obtain a formula for the conductance due to electron–electron interaction.

Since the results obtained in this article are not limited in a particular model, they may be applied to a variety of magnetic nanostructures.

II. LINEAR RESPONSE THEORY

Let us first consider a magnetic multilayer at zero temperature. The thickness of each layer is of the order of 10 Å. The mean free path of an electron, which is the relaxation time of momentum \times Fermi velocity, is estimated to be of the order of 100 Å from the value of the resistivity. Another

important length scale is the spin-diffusion length, which is the relaxation time of spin memory \times Fermi velocity. Although it is not easy to estimate it, this length is considered to be much longer than the mean free path. The above estimate indicates that the spin memory of an electron is conserved during the propagation through many layers. In other words, since each spin component of electrons contributes to the electric current almost independently, the so-called two-current model¹¹ works well. In the following, we study the conductance in the two-current model.

As seen in Fig. 1, the electric current is in the z direction and the total current (I) is given by integrating over the cross sectional area in the xy plane by

$$I = \int dS(z) \int d\mathbf{r}' \sum_{\nu} \sigma_{z\nu}(\mathbf{r}, \mathbf{r}') E_{\nu}(\mathbf{r}'), \quad (1)$$

$$\mathbf{E}(\mathbf{r}') = -\nabla' V(\mathbf{r}'), \quad (2)$$

with \mathbf{E} and V being the electric field and electro-static potential, respectively. Here, the total current is independent of the position z because of the current conservation. The non-local conductivity¹⁰ is given by the commutator of the current operator,

$$\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}') = \lim_{\omega \rightarrow 0} \frac{1}{\omega} \int_0^{\infty} dt \exp(i\omega t) \langle [j_{\mu}(\mathbf{r}, t), j_{\nu}(\mathbf{r}', t)] \rangle, \quad (3)$$

$$\mathbf{j}(\mathbf{r}) = \frac{e\hbar}{2im} \{ \psi^{\dagger}(\mathbf{r}) \nabla \psi(\mathbf{r}) - [\nabla \psi^{\dagger}(\mathbf{r})] \psi(\mathbf{r}) \}, \quad (4)$$

where $\langle \dots \rangle$ denotes the expectation value in the ground state and e and m are the electric charge and the effective mass of an electron, respectively. The field operator $\psi(\mathbf{r})$ is expressed

FIG. 1. Sample and leads for measuring conductance.

in the mean field theory by using the wave-function $\phi_{n\sigma}(\mathbf{r})$ and annihilation operator $c_{n\sigma}$ in the eigen-state n with spin σ as

$$\psi(\mathbf{r}) = \sum_n \sum_\sigma \phi_{n\sigma}(\mathbf{r}) c_{n\sigma}. \quad (5)$$

Inserting Eq. (5) into Eq. (4) and rewriting Eq. (3), we have

$$\sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}') = \pi \hbar e^2 \sum_{m,n} \sum_\sigma J_{nm\sigma}^\mu(\mathbf{r}) J_{mn\sigma}^\nu(\mathbf{r}') \times \delta(\epsilon_F - \epsilon_{n\sigma}) \delta(\epsilon_F - \epsilon_{m\sigma}), \quad (6)$$

$$J_{nm\sigma}^\mu(\mathbf{r}) = \frac{\hbar}{2im} \left[\phi_{n\sigma}^*(\mathbf{r}) \frac{\partial}{\partial x_\mu} \phi_{m\sigma}(\mathbf{r}) - \left(\frac{\partial}{\partial x_\mu} \phi_{n\sigma}^*(\mathbf{r}) \right) \phi_{m\sigma}(\mathbf{r}) \right], \quad (7)$$

where ϵ_F and $\epsilon_{n\sigma}$ are the Fermi energy and eigen-value in the state n with spin σ , respectively. We note that the wave-function satisfies the Schrödinger equation,

$$\left(-\frac{\hbar^2}{2m} \nabla^2 + U_\sigma(\mathbf{r}) \right) \phi_{n\sigma}(\mathbf{r}) = \epsilon_{n\sigma} \phi_{n\sigma}(\mathbf{r}), \quad (8)$$

where $U_\sigma(\mathbf{r})$ is the spin-dependent potential. As seen in Eq. (6), the conductivity is given by electrons on the Fermi level at zero temperature.

In one-dimension, examining the derivative, $dJ_{nm\sigma}/dz$, we find that the nonlocal conductivity is constant; $\sigma(z, z') = \sigma_0$. Then, we obtain

$$I = \sigma_0 V, \quad (9)$$

where V is the voltage between leads.

In three-dimension, examining the derivative, $\sum_\mu \partial J_{nm\sigma}^\mu(\mathbf{r}) / \partial x_\mu$, we find

$$\sum_\mu \frac{\partial}{\partial x_\mu} \sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}') = \sum_\nu \frac{\partial}{\partial x'_\nu} \sigma_{\mu\nu}(\mathbf{r}, \mathbf{r}') = 0. \quad (10)$$

Therefore, integrating Eq. (1) by parts, changing the integral over the volume to that of the boundary of the sample and noting that the current flows out of the leads but not of insulating boundary, we obtain

$$I = V \int dx dy \int dx' dy' \sigma_{zz}(\mathbf{r}, \mathbf{r}'), \quad (11)$$

where the total current depends on neither z nor z' . As seen in Eq. (11), the total current is independent of the detailed distribution of the electric field \mathbf{E} in the sample but depends just on the voltage between leads as also shown in one-dimension.

The conductance in Eq. (11) is given by the wave-functions of electrons on the Fermi level, which depend on the nanostructure as well as magnetic structure in the sample. Once the geometry of the sample and the magnetic structure are given, the conductance is calculated. We note that the sample may include an insulating layer. Thus, Eq. (11) is applied to tunneling junctions as well.

FIG. 2. Model of single resistive layer. Shaded layer denotes resistive layer.

III. EFFECTS OF ELECTRON-ELECTRON INTERACTION

In Sec. II, the conductance has been derived in the mean field theory. In this section, effects of the electron-electron interaction on the conductance is examined. For this purpose, we set up a model: we consider the tight binding model in a simple cubic lattice which contains a single resistive layer at $z=0$ as shown in Fig. 2. The z axis is chosen to be parallel to the (001) axis of simple cubic structure. In the layer, there exists the electron-electron interaction on each site given by the Hamiltonian,

$$H' = U \sum_l n_{l\uparrow} n_{l\downarrow}, \quad (12)$$

where $U > 0$ and $n_{l\sigma}$ is the number operator with spin σ at site l in the layer.

We calculate the self-energy with spin σ , $\Sigma_\sigma(\epsilon_F + i0)$, in the single site coherent potential (or Hubbard) approximation (CPA). In the approximation, $\Sigma_\sigma(\epsilon_F + i0)$ is finite in the layer, independent of the momentum in the xy plane and diagonal in the spin space. Thus, the effective Hamiltonian may be written as

$$\hat{H} = -t \sum_{(i,j)} \sum_\sigma c_{i\sigma}^\dagger c_{j\sigma} + \sum_l \sum_\sigma \Sigma_\sigma c_{l\sigma}^\dagger c_{l\sigma}, \quad (13)$$

where t is the hopping parameter between nearest neighbor sites. Using the effective Hamiltonian [Eq. (13)], the transmission and reflection coefficients of electrons are calculated in the usual way¹² as

$$T_{\text{coh}}^\sigma = \frac{4t^2 \sin^2 \theta_{\mathbf{k}}}{(2t \sin \theta_{\mathbf{k}} + i \Sigma_\sigma)(2t \sin \theta_{\mathbf{k}} - i \Sigma_\sigma^*)}, \quad (14)$$

$$R_{\text{coh}}^\sigma = \frac{\Sigma_\sigma \Sigma_\sigma^*}{(2t \sin \theta_{\mathbf{k}} + i \Sigma_\sigma)(2t \sin \theta_{\mathbf{k}} - i \Sigma_\sigma^*)}, \quad (15)$$

where $\mathbf{k} = (k_x, k_y)$ is the wave number in the xy plane and $\theta_{\mathbf{k}}$ is defined as $-2t \cos \theta_{\mathbf{k}} = \epsilon_F + 2t(\cos k_x + \cos k_y)$. Here, T_{coh}^σ and R_{coh}^σ are the coherent part of transmission and reflection coefficients, respectively. Since there exists the imaginary part in the self-energy in the resistive layer, electrons are caught in the layer and then diffuse from it. Such diffusive motion of electrons is incoherent. When the incoherent transmission and reflection coefficients are written as T_{in}^σ and R_{in}^σ , respectively, the current conservation is written as

$$T_{\text{coh}}^\sigma + R_{\text{coh}}^\sigma + T_{\text{in}}^\sigma + R_{\text{in}}^\sigma = 1. \quad (16)$$

Following Stone and Lee,¹³ we assume that electrons caught in the layer diffuse incoherently into the both sides equally and have

$$T_{\text{in}}^{\sigma} = R_{\text{in}}^{\sigma} = \frac{1}{2}(1 - T_{\text{coh}}^{\sigma} - R_{\text{coh}}^{\sigma}). \quad (17)$$

Therefore, using the Landauer formula, we obtain the conductance as

$$\sigma_{zz} = \frac{e^2}{h} \sum_{\mathbf{k}} \sum_{\sigma} (T_{\text{coh}}^{\sigma} + T_{\text{in}}^{\sigma}), \quad (18)$$

$$T_{\text{in}}^{\sigma} = \frac{it \sin \theta_{\mathbf{k}} (\Sigma_{\sigma} - \Sigma_{\sigma}^*)}{(2t \sin \theta_{\mathbf{k}} + i \Sigma_{\sigma})(2t \sin \theta_{\mathbf{k}} - i \Sigma_{\sigma}^*)}. \quad (19)$$

We can show that Eq. (18) is also derived from the Kubo formula [Eq. (1)] in the single site CPA (Ref. 12) without introducing the above assumption for the incoherent motions of electrons. In this case, the self-energy and vertex correction must be calculated consistently to satisfy the current conservation. When the single site CPA is used in the system with random scattering potentials, the elastic scattering is replaced by the inelastic one and the phase coherence of electrons is destroyed. However, it has been shown¹² that the conductance [Eq. (18)] agrees with that given by the numerical simulation with any strength of random scattering potentials. Therefore, the CPA may be used for the calculation of the conductance.

IV. DISCUSSION

We have studied the conductance in magnetic nanostructures. When the electron-electron interaction is neglected, the conductance depends only on the voltage between leads. Therefore, it is calculated once the nanostructure and magnetic structure are given in the sample. Although it is not easy to obtain the analytical solution of the conductance, the numerical simulation has been done extensively in a variety of the nanostructures.¹⁴⁻¹⁶

In the tunneling junctions, the insulating barrier is usually made by oxides so that the energy gap is caused by the electron correlation. We have introduced the electron-electron interaction in the single resistive layer and obtained the conductance due to the interaction. The application of Eq. (18) to the realistic junctions will be presented separately.

Finally, the theory obtained in this article is limited in the two-current model. Although the model works well at low temperatures, the spin-flip scattering will not be neglected as temperature increases. Effects of the scattering will also be studied separately.

Spin-dependent tunneling effect and GMR in metal–nonmetal granular systems (invited) (abstract)

H. Fujimori and S. Mitani

Institute for Materials Research, Tohoku University, Sendai 980-77, Japan

S. Ohnuma

The Research Institute of Electric and Magnetic Materials, Sendai 982, Japan

Giant magnetoresistance (GMR, large negative and isotropic magnetoresistance) arising from a spin-dependent tunneling effect has been found in metal–nonmetal granular systems exhibiting extremely high electrical resistivities.¹ These granular materials are reactively sputtered Co–(Al, Si)–O and Fe–Mg–O thin films, having a two phase nanostructure consisting of the Co (or Fe) rich metallic and magnetic grains and the Al (or Si, Mg) oxide narrow intergrains. These films possess large specific electrical resistivities (ρ_0) of 10^4 – $10^6 \mu\Omega \text{ cm}$ at room temperature, and show remarkable magnetoresistance ($\Delta\rho/\rho_0$) whose values are about 8% in maximum at room temperature and at about 10 kOe of applied magnetic field. With decreasing temperature, $\Delta\rho/\rho_0$ and ρ_0 increase. The temperature dependence of ρ_0 can be expressed in terms of $\log \rho_0 \propto T^{-1.2}$, and the electrical current versus applied electrical voltage does not follow the ohmic law. We consider that a spin-dependent tunneling conductance in the path of magnetic grains–nonmetallic intergrains–magnetic grains is responsible for the observed GMRs accompanying high electrical resistivities. The details of these transport properties and the related magnetization and structural properties will be presented. © 1996 American Institute of Physics. [S0021-8979(96)59708-3]

Spin-dependent transmission of free electrons through ultrathin cobalt layers (invited)

H.-J. Drouhin, A. J. van der Sluijs, Y. Lassailly, and G. Lampel

Laboratoire de Physique de la Matière Condensée, Centre National de la Recherche Scientifique, Ecole Polytechnique, 91128 Palaiseau, France

We present an original technique to investigate spin-dependent electron interactions in ferromagnetic metals, and place it in the context of previous studies. Our technique is based on spin-polarized electron transmission through ultrathin, free-standing, metal foils. A longitudinally spin-polarized, quasimonoenergetic, free-electron beam impinges onto a ferromagnetic target consisting of a few atomic layers of cobalt sandwiched between gold layers, for an overall thickness of the order of 25 nm. It is remanently magnetized perpendicular to the film plane. The current transmitted through the foil is energy analyzed and its dependence on the relative orientation between the spin polarization of the primary beam and the magnetization direction of the cobalt layer is measured. The experiments are performed over a wide primary energy range, starting from the vacuum level of the target; the work function of the target can be lowered down to 2 eV by cesium deposition. We demonstrate a spin-filter effect, favoring the transmission of majority electrons. It is very large at low primary energy, when the electrons travel close to the 3d bands. Perspectives for compact and highly discriminative spin detectors are discussed. © 1996 American Institute of Physics. [S0021-8979(96)50408-8]

I. INTRODUCTION

The physics of ultrathin magnetic layers is an active field of research, generally involving magnetoresistive and magneto-optical properties.^{1,2} Novel magnetic sensors and heads are under development³ and electron devices making use of "spin valve" effects are emerging.^{4,5} We will consider a different but complementary approach, based on the spin-dependent transmission of free electrons through self-supported magnetic structures. Earlier accounts on this work can be found in Refs. 6–8.

Pioneering low-energy transmission experiments were performed by Kanter⁹ who studied electron transmission through aluminum, gold, and silver foils to explore the energy dependence of the electron mean free path. Practically, free-standing foils can hardly be thinner than 20 nm and, because the electron mean free path is at most of the order of 2 nm, the transmitted intensity does not exceed a few 10^{-5} of the primary beam. It should be emphasized that such measurements are extremely difficult because the relevant parameter is this small transmission ratio, which can be affected by different factors, notably the foil quality. This type of measurement can also be compared to photoemission experiments: a substrate photoemission peak is selected and its attenuation is monitored as a function of a growing overlayer thickness. Whatever the technique, measuring electron mean free paths is intricate. Nevertheless, from the conductivity relaxation time, we know that, at very low energies, close to the Fermi level, the mean free path is long (tens of nm) whereas surface analysis techniques using electron beams demonstrate that, at much higher energies, the mean free path compares to the thickness of a few atomic layers. In all these experiments, the elastically emitted electrons can be unambiguously isolated, so that the mean free path which is measured is the *inelastic* mean free path. It characterizes the electron scattering out of the primary beam.

In this paper, we only consider the spin dependence of the transmitted intensity, which is a more reliable feature. The primary electron beam has a longitudinal spin polarization and impinges normally onto a cobalt layer sandwiched between gold layers, a ferromagnetic structure with a magnetization perpendicular to the film plane. We measure a transmission asymmetry between the incident electrons with spin parallel or antiparallel to the majority spin direction in the sample. Following Schönhense and Siegmann,¹⁰ we can say that our structure acts as a "spin filter." Spin-dependent transmission has also been previously studied in photoemission experiments by the overlayer technique.¹¹ Generally, in these experiments, unpolarized electrons are injected from a substrate core level into the magnetic overlayer; due to spin-dependent transport a spin polarization builds up and the measured parameter is the spin polarization of the emitted beam. In an experiment closely related to our transmission technique, Gröbli *et al.*¹² studied the spin dependence of the current photoemitted from a gallium arsenide crystal covered with an Ag/Fe bilayer. There, by optical pumping, spin-polarized electrons are generated inside the semiconductor, with a spin polarization parallel to the direction of the exciting light, normal to the surface. The photoelectrons are subsequently extracted through the ferromagnetic overlayer. Such a solid-state structure, which associates the electron source to the magnetic target in a same device, is attractive, but the technology strongly constrains the experimental conditions: an Ag buffer layer has to be inserted to prevent interdiffusion and chemical reactions, and the magnetization has no perpendicular remanence so that the continuous application of a high magnetic field (± 1.6 T) is required to maintain the magnetization normal to the surface. A practical complication also arises due to the contribution of the metal layer itself to the photoemission current, which is responsible for a large background signal. A similar background contribution is present in all photoemission experiments and re-

stricts the study to a very precise range of metal thicknesses which does not allow one to discriminate between interface and bulk effects. Another device, called the "spin-valve transistor," has recently been elaborated.⁵ It acts as a "hot-electron spectrometer" for the study of the magnetic interactions and possibly allows one to control the electron energy in the 0.3–3 eV range above the Fermi level. Generally speaking, in solid-state structures the effects may be more difficult to disentangle than in transmission experiments. A clear advantage of our technique is that we control the primary energy and polarization and can also analyze the transmitted beam, in energy and possibly in spin polarization. It is a very direct way to investigate spin-dependent interactions in ferromagnetic metals, a topic where the microscopic detail remains questioned. A transmission experiment is obviously restricted to electron energies exceeding the vacuum level, about 4 eV above the Fermi level for a clean gold surface, but a surface treatment by cesium deposition lowers it down to 2 eV. As magnetoresistance experiments probe the spin-dependent interactions at the Fermi level, and as some structures like the spin-valve transistor may cover intermediate energies, a complete investigation appears within reach.

Concerning applications, we will show that our spin-filtering foils constitute a new kind of spin detector, based on the exchange asymmetry. This has interesting implications because, if the electron spin is currently used as a probe of electronic and magnetic properties of solids, the spin measurement remains a bottleneck. In recent years, considerable effort has been put into the improvement of polarimeters, but an efficient, easy to use, spin detector remains to be found. Even now Au/Co/Au structures can compete with the best existing spin detectors.

II. BACKGROUND

For many years spin-polarized electron techniques have been intensively developed for the study of magnetic interactions.¹³ Essentially, two types of experiments have to be distinguished: (i) experiments where the spin polarization of the beam after interaction with the ferromagnetic target is detected; (ii) experiments in which the primary beam is spin-polarized, and where the spin dependence of the electron current is the relevant parameter. Now, we will compare these two classes of experiments in the framework of a very simple model.

We assume that electrons are injected into a ferromagnetic foil and cross it to be reemitted into vacuum. The electron source emits a constant number of electrons $N = (n_+ + n_-)$ per unit of time and has a spin polarization $P_S = (n_+ - n_-)/(n_+ + n_-)$, where $n_+(n_-)$ is the number of electrons with spin up (down) with respect to a fixed reference axis, parallel to the magnetization direction; the absolute value of P_S is denoted as P . We only consider spin-dependent electron transport toward the surface and assume that the number of electrons reaching the surface with spin up (down) is $t_{\sigma+}n_+(t_{\sigma-}n_-)$; here $t_{\sigma+}(t_{\sigma-})$ are transport coefficients affected to up (down) spin and $\sigma = \pm$ indicates the majority spin direction in the ferromagnet. As the spin-dependent interactions depend only on the relative orienta-

FIG. 1. Graphical determination of the emitted electron polarization.

tion of the incident spins with the majority spin direction in the ferromagnet, we have the symmetry relations $t_{++} = t_{--}$ and $t_{+-} = t_{-+}$; for simplicity, we will sometimes use the notation $t_{++} = T_+$ and $t_{+-} = T_-$. The spin polarization of the electrons reaching the surface, which we assume to be the emitted beam polarization, is $P_e = (P_S + a_\sigma)/(1 + a_\sigma P_S)$, where a_σ is the spin asymmetry of the transport coefficients defined by $a_\sigma = (t_{\sigma+} - t_{\sigma-})/(t_{\sigma+} + t_{\sigma-})$. In the following, we will also speak of the asymmetry $a = a_+ = (T_+ - T_-)/(T_+ + T_-)$; we will see from general arguments that a should be positive. For analysis, it is convenient to define the parameters x_S and α_σ by the relations $P_S = \tanh x_S$ and $a_\sigma = \tanh \alpha_\sigma$. Then $P_e = \tanh(x_S + \alpha_\sigma)$, which allows its simple graphical determination, knowing the source polarization and the spin asymmetry of the transport process (see Fig. 1).

To give an example, consider the work by Penn and co-workers:¹⁴ an unpolarized electron beam impinges on a ferromagnetic glass with sufficient energy to excite a secondary electron cascade, with a spin polarization reflecting the bulk magnetization (about 0.2). The question was to explain the enhanced polarization of the low-energy secondaries (about 0.4 at the vacuum level). In this case, spin-polarized electrons are generated inside the ferromagnet by impact excitation and the polarized electron source with polarization $P_S = 0.2$ lies within the ferromagnet. When the electrons are emitted at an energy not too far from the d bands, the lifetimes for majority and minority electrons differ. These lifetimes are interpreted as T_+ and T_- ; this defines the spin asymmetry a for the emission process, and thus P_e . Here obviously, the spin polarization of the source cannot be reversed independently of the target magnetization.

Coming back to our experiment, we start with a positive spin polarization of the source and inject $n_+ = (N/2)(1 + P)$ electrons with spin up and $n_- = (N/2)(1 - P)$ electrons with spin down, so that the transmitted beam intensity is $I_\sigma^+ = (N/2)[t_{\sigma+}(1 + P) + t_{\sigma-}(1 - P)]$ for a given magnetization of the layer. Reversing the sign of the polarization, the transmitted intensity becomes $I_\sigma^- = (N/2)[t_{\sigma+}(1 - P) + t_{\sigma-}(1 + P)]$. The asymmetry in the transmitted intensity is then $\mathcal{A}_\sigma = (I_\sigma^+ - I_\sigma^-)/(I_\sigma^+ + I_\sigma^-) = a_\sigma P$; we will note $\mathcal{A} = \mathcal{A}_+ = aP$.

In this model, the spin polarization of the transmitted beam P_e and the asymmetry in the transmitted intensity \mathcal{A}_σ are closely related. Nevertheless, the conditions in which the

experiments have to be performed are opposite: to determine the asymmetry a_σ of the transport process, an unpolarized source has to be preferred when performing spin-polarization measurements (case i), whereas a highly polarized source should be used if the spin-dependent intensity is measured (case ii). In real experiments, however, a strong change in the emitted beam polarization does not necessarily mean any related effect in the transmitted intensity: for instance, secondary electrons have a polarization which reflects the bulk magnetization but they may have no "memory" of the spin polarization of the primary beam. In fact, spin polarization and transmitted intensity measurements appear to be complementary.

When electrons travel through a ferromagnetic film of thickness d and only bulk effects are taken into account, it is usual to relate the spin-dependent transport coefficients to the spin-dependent inelastic mean free paths $\lambda_+(\lambda_-)$ for majority (minority) spin electrons through $T_\pm = \exp(-d/\lambda_\pm)$. Thus $a = \tanh[(d/2)(\lambda_-^{-1} - \lambda_+^{-1})]$; the transmission factor, the ratio of the transmitted (I) to the primary (I_0) intensity, takes the form $I/I_0 = \cosh[(d/2)(\lambda_-^{-1} - \lambda_+^{-1})] \exp[-(d/2)(\lambda_-^{-1} + \lambda_+^{-1})]$. The spin asymmetry of the mean free path $(\lambda_+ - \lambda_-)/(\lambda_+ + \lambda_-)$ is often considered and values ranging from 0.1 to 0.3 have been found at a few eV above the vacuum level for 3d-transition metals.¹⁰

To go further in the analysis, we need a model to determine the spin-dependent transport coefficients. Because there is a larger number of empty states near the Fermi level for minority spin electrons, i.e., more relaxation channels, the majority spin electrons should be more easily transmitted. The simplest formulation was given by Schönhense and Siegmann.¹⁰ For noble or transition metals these authors assume that the electron scattering cross section, which is proportional to the inverse of the electron mean free path, is directly related to the number of unoccupied states in the d band. This leads to different cross sections for majority and minority spin electrons, with the relation $\lambda_\pm^{-1} = \lambda_0^{-1} + \lambda_d^{-1} [5 - (n \pm \Delta n)]$; here λ_0^{-1} and λ_d^{-1} are suitable coefficients and $n \pm \Delta n$ is the number of occupied states in the d band for majority and minority spin electrons. This simple theory gives fair agreement with presently available experimental data, at least for energies above the vacuum level. Yet many aspects remain to be cleared, for instance, the energy dependence of the scattering cross section or the comparison between different metals, because some results obtained in photoemission and in magnetoresistance experiments appear contradictory.¹⁵ In our experiment, speaking in terms of mean free path, the measured asymmetry is directly related to $1/\lambda_- - 1/\lambda_+$, a physical quantity proportional to the magnetic moment. Unless performing absolute intensity measurements, which are extremely difficult, we cannot determine independently λ_- and λ_+ . It will be useful in the following to write $1/\lambda_+ = 1/\lambda - 1/\delta$ and $1/\lambda_- = 1/\lambda + 1/\delta$ which defines the spin-averaged mean free path λ by $1/\lambda = (1/2)[1/\lambda_- + 1/\lambda_+]$. Then the spin asymmetry of the mean free path is λ/δ and, at energies above the vacuum level, we expect $\delta \gg \lambda$, with λ of the order of 1 nm.¹⁰ The asymmetry a and the transmission ratio I/I_0 take simple forms, $a = \tanh(d/\delta) \sim (\lambda/\delta)(d/\lambda)$ and

$I/I_0 = \cosh(d/\delta) \exp(-d/\lambda) \sim \exp(-d/\lambda)$, for an ultrathin layer ($d \ll \delta$); in our experiment $d/\lambda \approx 1$.

III. EXPERIMENT

The experimental setup has been described in detail elsewhere.⁸ A longitudinally spin-polarized electron beam is obtained from a GaAs photocathode under optical pumping. This beam, whose polarization is modulated between +0.24 and -0.24, is focused on a ferromagnetic sample, remanently magnetized perpendicular to its surface. The current transmitted through the sample is energy-analyzed using a retarding-field analyzer (resolution 150 meV) and its polarization dependence is measured. Stray modulations are maintained at a relative level below a few times 10^{-4} . The sample's magnetization is reversed in the measurement configuration by a magnetic-field pulse. The sample holder can be cooled down to about 130 K by contact with a liquid-nitrogen cold finger. The primary electron energy E_p is continuously varied from the sample's vacuum level upward. Throughout the paper the energy is measured with respect to the Fermi level of the ferromagnetic structure.

We will present results on three nearly identical ferromagnetic structures, labeled A, B, and C. Each consists of a 1-nm-thick layer of cobalt sandwiched between gold layers: Au(21 nm, 22 nm, 22 nm)/Co(1 nm)/Au(2 nm) for structures A, B, and C, respectively. The primary beam impinges on the thicker gold layer. Details about the sample preparation can be found in Ref. 6. To obtain a free-standing sample, the Au/Co/Au films are evaporated on a float glass substrate with an intermediate layer of NaCl. Then the metal foil is lifted off in water and deposited onto a gold-plated copper sample holder with an aperture of about 3 mm diameter.

To explore a lower energy domain, we reduce the work function of the structures by cesium deposition, a well-known technique. Although cesium reacts with gold,¹⁶ this is not of importance here as we are not concerned by the surface electronic structure. Practically, cesium is evaporated until a photoemission current is measured when the target is illuminated by a red laser diode, which means that the vacuum level has been lowered from 4 to about 2 eV above the Fermi level. The "activated" surface remains stable over a long time (several weeks). The amount of cesium deposited should be of the order of an atomic layer. Once deposited, cesium cannot be removed from the surface by subsequent treatment.

IV. THE SPIN-DEPENDENT TRANSMITTED CURRENT

A careful study of reference gold samples has been previously performed; the results and a comparative discussion with data by Kanter (Ref. 9) can be found in Ref. 8. Here we present results obtained at room temperature on Au/Co/Au structures with clean and cesiated surfaces; some results at lower temperature (130 K) are also given. The experimental curves are normalized to an incident current of 100 nA.

A. Principle of the measurement

The transmitted current measured as a function of the retarding potential at $E_p = 3.8$ eV, from structure C with a

FIG. 2. Structure C, cesiated exit face. Transmitted current vs retarding potential for $E_p = 3.8$ eV (curves a and b) and 2.9 eV (curve c). In the two upper curves, whose zero signal levels have been shifted for clarity, the spin polarization of the primary beam is switched periodically from $+0.24$ to -0.24 and the steps are the corresponding variations of the transmitted current.

cesiated exit surface, is shown in Fig. 2, curve (a). To understand this curve, remember that, for a retarding potential corresponding to a cutoff at energy E , the collected current is $I(E) = \int_E^{+\infty} \delta I(E') dE'$, where $\delta I(E')$ is the energy distribution of the transmitted current. Two main features are observed: a high-energy edge and a low-energy step. The high-energy edge, whose position varies linearly with E_p , corresponds to ballistic electrons or to electrons which experienced only small energy loss or momentum change throughout the foil ("quasielastic" part). The low-energy step ("inelastic" part) originates from electrons which have lost a notable part of their energy or from true secondary electrons, emitted with a negligible kinetic energy, at the surface vacuum level. The relative intensities of these two contributions depend on E_p ; when E_p is close to the vacuum level, the elastic and inelastic parts cannot be separated. The total transmitted current is of the order of 10^{-4} of the primary beam. At higher E_p , the inelastic step is increased by a large amount, due to secondary electron generation. Information on the inelastic mean free path is contained in the high-energy edge, where true elastic electrons are detected.⁸

Information on the spin-dependent interactions is obtained from the difference in the transmitted intensity between both incident spin directions. The principle is made clear when looking at Fig. 2, curves (b) and (c), which visualize the transmitted intensity versus retarding potential at low primary energies [$E_p = 3.8$ and 2.9 eV, respectively]. During the scan, the spin polarization of the source is switched periodically from $+0.24$ to -0.24 and the steps are the corresponding variation of the transmitted intensity, which is very large, especially at the lowest primary energy where the total transmitted intensity also increases due to the larger electron mean free path. At a given time, indicated by the arrow in curve (c), the magnetization of the film has been reversed by a pulse of field, so that the signal levels corresponding to the two incident spin orientations are exchanged.

FIG. 3. Structure A with cesiated entrance and exit faces. Transmitted current (upper curve) and the corresponding DTCs for $E_p = 6.4$ eV, for two opposite magnetizations of the cobalt layer.

As expected, the majority spin electrons are more easily transmitted. Practically, it is more convenient to use lock-in detection techniques to measure directly the intensity difference, that we call the spin-dependent differential transmitted current (DTC) $\Delta I_\sigma = \int_E^{+\infty} [\delta I_\sigma^+(E') - \delta I_\sigma^-(E')] dE'$, where $\delta I_\sigma^+(E') [\delta I_\sigma^-(E')]$ is the energy distribution of the transmitted current for incident electron spin polarization parallel (antiparallel) to the electron-beam propagation axis Oz and for majority spin in the ferromagnet parallel ($\sigma = +$) or antiparallel ($\sigma = -$) to Oz . In Fig. 3 (structure A, cesiated), the DTC measurements are shown for the two opposite magnetizations of the layer and the symmetry of the resulting curves with respect to the zero signal level is a test for the absence of instrumental asymmetry. As expected a zero DTC is measured when starting with a nonmagnetized structure. Then magnetic-field pulses are applied in order to saturate the DTC. Now, the intensity transmission asymmetry \mathcal{A} and the spin asymmetry of the transport coefficients a depend on both E_p and on the transmitted electron energy E ; we will explicitly state this energy dependence by writing $\mathcal{A}(E_p; E)$ and $a(E_p; E)$. At a fixed E_p , we numerically differentiate the collected current and the DTC to obtain the energy distribution of the transmitted current and its spin asymmetry. According to Sec. II, $\mathcal{A}_\sigma(E) = [\delta I_\sigma^+(E) - \delta I_\sigma^-(E)] / [\delta I_\sigma^+(E) + \delta I_\sigma^-(E)]$ and $\mathcal{A}(E) = \mathcal{A}_+(E) = a(E)P$.

B. Results and discussion

Because large effects are observed at low electron energy, we will first consider the effects of lowering the vacuum level. Figure 4 shows the energy distribution curve (EDC) of the transmitted current from structure C with a clean and with a cesiated exit surface. The "entrance" face had not been intentionally cesiated, but the possibility to inject electrons at energies as low as 2.6 eV indicates some cesium contamination. The low-energy end of each EDC is determined by the vacuum level cutoff, which appears to be reduced by 2 eV after cesiation, giving access to lower electron energies. We observe that the work-function reduction leaves the elastic peak almost unaffected while a large inelastic peak appears which becomes the dominant contribution to

FIG. 4. Structure C with a clean surface (\blacklozenge) and a cesiated exit surface (\triangle). EDCs of the transmitted current obtained by numerical differentiation of the current collected after retardation for $E_p=5.4$ eV. The arrows indicate the locations of the vacuum level.

FIG. 5. Structure C, cesiated exit surface. EDC of the transmitted current (full symbols) and its spin dependence (open symbols) for $E_p=3.5$ eV (diamonds, single scan) and 5.4 eV (triangles, average of ten scans). For clarity, the base lines of the 3.5 eV curves have been shifted.

the transmitted current. At very low energy, the overall transmission is increased by more than an order of magnitude to reach 6×10^{-4} . In these conditions a spin asymmetry can be observed over an energy range of a few eV and it is possible to study precisely, at fixed E_p , the dependence of the transmission asymmetry on the transmitted electron energy E . Note that, at the Co layer, the initial conditions are well defined: in gold, the mean free path for spin relaxation is much longer than that for energy relaxation¹⁷ and no significant secondary electron contribution is expected at low E_p , so that the spin polarization is conserved after passing the Au layer; cesium deposition should not affect the spin polarization.¹²

Figure 5 shows the EDCs of the transmitted current and their spin dependence (structure C, cesiated) for $E_p=3.5$ eV (upper curves) and 5.4 eV (lower curves). In the EDCs the elastic and inelastic peaks are well resolved. For $E_p=5.4$ eV, the spin-dependent curve closely follows the inelastic peak, no elastic contribution to the asymmetry being observed in these conditions; this is evidence that $a(E)$ remains constant over the inelastic peak. For $E_p=3.5$ eV, a small spin-dependent transmission is observed in the elastic peak and the spin-dependent signal is increased in the inelastic peak. In general, striking features are the large difference in transmission between the two incident spin orientations at low E_p and the sharp decrease of the spin dependence when increasing E_p . At the lowest primary energies, the incident electrons are transmitted at an energy close to the 3d bands, and spin-dependent transmission is observed whatever the emerging electron energy. At higher energies, spin-dependent transmission only appears at the inelastic peak. Lowering the temperature to about 130 K increases the transmitted current by about 50%. This fact was already mentioned by Kanter, who reported an exponential variation of the transmitted current versus temperature;⁹ it was attributed to the temperature dependence of the electron-phonon interaction. The spin asymmetry is almost doubled in the elastic peak and does not change significantly in the inelastic peak. At 130 K, it be-

came technically impossible to reverse the magnetization, because of a too large increase of the coercive field.

We will first discuss the elastic peak, where we measured a maximum asymmetry $a \approx 0.13$ at $E_p \approx 5$ eV for structure A with a clean surface. In this region, we use the inelastic mean free path model presented in Sec. II and we deduce that $T_+/T_- \approx 1.3$; assuming a spin-averaged mean free path of the order of 1 nm in cobalt, this is also consistent with a mean free path asymmetry of about 0.13, a plausible value. However, further studies with other structures showed a sensitivity of the asymmetry in the elastic peak to the sample preparation. The analysis of these effects is under way. Now, because the asymmetry a is larger and constant over the inelastic peak we choose to plot its variation, as a function of E_p for structures A, B, and C, with clean or cesiated surfaces, at room temperature or at low temperature (Fig. 6). The results appear to be very reproducible and we see that a reaches extremely large values at low E_p and decreases rapidly with increasing E_p . The maximum value of a is about 0.6 which corresponds to $T_+/T_- = 4$. Strictly speaking, here a mean free path model does not apply. Nevertheless, for a low E_p , it should yield a reasonable estimate of some mean free path average, between the vacuum level and E_p . Therefore, in Fig. 6, an additional point is indicated at the lowest E_p , where the elastic and inelastic peaks can no longer be resolved; on the total current we measure again $a \approx 0.6$. Using this a value, we deduce a mean free path asymmetry of about 0.6, intermediate between the results obtained at a few eV above the clean surface vacuum level (0.25),¹⁰ and those estimated at the Fermi level in magnetoresistance experiments (about 0.7).¹⁵ Nevertheless, the detail of the electron transport in the inelastic part has to be analyzed prior to any more refined interpretation and at present a certain number of points remain unexplained, for instance, the very sharp decrease of the asymmetry with E_p , the larger asymmetry in the inelastic peak than in the elastic peak, even at ultralow

FIG. 6. Asymmetry a measured in the inelastic part of the transmitted current vs E_p for several structures and in various conditions. The point \boxplus is the asymmetry on the total transmitted current at $E_p=2.6$ eV, where the elastic and inelastic peaks are not resolved.

primary energy, and a small but reproducible reduction of the asymmetry, at given primary and analysis energies, after cesiation. It is clear that complementary experiments are necessary: let us mention the study of a structure where the primary beam impinges on the thinnest gold layer to clarify the role of the electron transport in the gold cap layers, the study of multilayers to discriminate between bulk and interface effects, and the spin analysis of the transmitted beam to determine the origin of the inelastic electrons.

V. CONCLUSION AND PERSPECTIVES

Magneto-optics and magnetoresistance are well established techniques which provide spectacular effects on (complicated) layered structures. Similar systems and also simple model structures, where many parameters are under control, can be studied by spin-polarized electron transmission, in a truly direct way. Our results show spin asymmetries which can be extremely large, but the technique is still in its infancy. We are convinced that, in a near future, it will yield new insight in the microscopic detail of spin-dependent electron interactions in ferromagnetic metals. Let us conclude with spin detectors. A polarimeter is generally characterized by the figure of merit $F=S^2/I(I_0)$, where $I(I_0)$ is the collected (incoming) current and S the Sherman function which expresses the scattering asymmetry. $1/F$ is almost proportional to the time needed to perform a polarization measurement with a given accuracy. For the traditional Mott polarimeter operating at an energy of 100 keV, S is typically 0.3 and F at best of the order of 10^{-4} . The data obtained on a cesiated Au/Co/Au sandwich (at low temperature) can be expressed in terms of spin detectors, identifying S to a : they correspond to $S=0.6$ and $F=1.7 \times 10^{-4}$; this figure of merit is one of the highest ever reported. A more detailed comparison with other recently developed detectors is given in Ref. 7. In our simple structure, only a small improvement (35%) of F

can be expected by optimizing the thickness of the ferromagnetic layer. The expressions of a and I/I_0 given in Sec. II show that the figure of merit for the sole cobalt layer is of the order of $(\lambda/\delta)^2(d/\lambda)^2 \exp(-d/\lambda)$, so that an optimum is reached for $d \sim 2\lambda$ (about 2 nm), and in any case, we are restricted to thicknesses for which the magnetization remains perpendicular ($d \leq 15$ Å). Because the transmitted current decreases exponentially over a characteristic length equal to the electron mean free path, i.e., about 2 nm, a much larger improvement can be expected from the improvement of I/I_0 when reducing even slightly the thickness of the gold layer. The use of cobalt multilayers should also be considered. When very small asymmetries have to be measured, the limiting factor is not the statistical noise but the sensitivity to instrumental asymmetries. Then, the high analyzing power that is expressed by a large S is a key feature and the detector quality cannot be reduced to an F value. The large Sherman function of our structure, the easy elimination of any instrumental asymmetry by magnetization reversal, and the possibility to operate in the electron counting mode make it very promising as a spin detector.

ACKNOWLEDGMENTS

We thank C. Marlière for his precious contribution in the early stage of the experiment, J.-P. Chauvineau for continuous support in sample growth and characterization, and F. Bridoux for his help with grazing incidence x-ray reflectometry. We are indebted to M. I. D'yakonov for many stimulating discussions. H.-J. D. thanks the "Direction de la Recherche et de la Technologie de la Délégation Générale pour l'Armement" for his support. A. J. v. d. The vibrating sample magnetometer: Experiences of a volunteer (invited)

S. Foner

Francis Bitter National Magnet Laboratory and Department of Physics, MIT, Cambridge, Massachusetts 02139

On its 40th anniversary, I describe how the vibrating sample magnetometer (VSM) was developed and, later, how the very low frequency VSM, a flux-integration device, was developed. The important features of the moving sample technique, detection coil symmetry, calibration, sensitivity, and image effects are discussed briefly. Some VSM adaptations discussed include operation at ^3He and dilution refrigerator temperatures, at high hydrostatic pressures, in superconducting, high-power water-cooled and hybrid magnets, for very low frequency ac susceptibility, and with SQUID detectors. © 1996 American Institute of Physics. [S0021-8979(96)50508-4]

I. THE VIBRATING SAMPLE MAGNETOMETER (VSM)

The VSM and the Magnetism and Magnetic Materials Conference (M^3) are both celebrating their 40th anniversary. It is no surprise that the M^3 conference is still active and productive because magnetism continues to be important in basic science and in major industrial markets. However, the chance that a magnetic measurement instrument would continue to be popular is small, considering that often there appears to be more ways to measure magnetic properties than there are magneticians. Here I outline how two different VSMs were developed and discuss some of the many subsequent adaptations.

Science is not done in the logical manner presented in published papers. Often, chance or incidental factors lead to significant changes in direction. This was the case for the VSM. I arrived at Lincoln Laboratory during the early days of the Cold War. It was a classified laboratory, managed by MIT, that grew out of the war-time Radiation Laboratory at MIT and was dedicated to the US Electronic Air Defense. I was doing basic research in an applied physics group developing microwave ferrite devices for radar applications such as isolators, circulators, and Faraday rotators that capitalized on the gyrotropic properties of insulating ferrites in a magnetic field. The group, headed by Benjamin Lax, included Joseph Artman and Peter Tannenwald doing ferromagnetic resonance, and Kenneth Button, Stanley Autler, and Herbert Zeiger among others. At that time ferrites were fairly new and the magnetization of specific materials was needed for calculations of the microwave propagation in the devices. I had been involved in magnetism for my thesis and volunteered to measure the magnetization for these materials. First I used flux integration, detected by a coil surrounding the ferrite bar on reversal of the magnetic field. This required modifying a 12 in. Varian electromagnet by incorporating a time-delayed reversing switch. (The early magnets were sold for nuclear magnetic resonance which required a fixed, stable field. Our outstanding and large proportioned sales representative, "Tiny" Yewell of Yewell Associates, forwarded our magnet modifications and these often would appear some-

time later in the Varian product line.) Then I built a modified classic Sucksmith ring balance¹ to measure the force on a small sample in a well-defined magnetic field gradient. The ring balance used two facing mirrors mounted on a very thin Cu-Be circular spring. The force on the spring deformed the ring so that the deflection of a light beam reflected between the mirrors was magnified when projected at some distance. This was a fairly rugged device. Then the group moved to new space in Bedford, MA and occupied a wooden radar field station, and anyone walking on the wooden floor caused the light beam to bounce erratically. Despite this limitation, data could be obtained. Just before the summer of 1955, we moved again, this time to a garage attached to the main building of the new laboratory and near a small lunch room on the next floor.

David J. Robbins, a bright young Harvard physics graduate student, joined the group for the summer to work with me on these measurements. Unfortunately, he was killed during a lunch break while testing a high-performance motorcycle on a nearby, new, unopened road. I remember the sad weekend at the end of the summer when my wife and I drove to New York for his funeral through the debris deposited just after the third of three successive hurricanes that chose routes through Boston on alternate weeks.

That summer we were living in a small farm-hand's house about 1 km from the laboratory and just off the runway at Hanscom Field, a Strategic Air Command (SAC) base at that time. While shaving one evening I decided to try ac induction for magnetic measurements. With some Duco cement, a small \$2.00 (in 1955) replacement loudspeaker, a conical paper cup, and a paper straw (the latter components were light and conveniently available at night from the lunch room), the first working model VSM was assembled. Initial test of principle was made using a reduced amplitude 60 Hz line excitation of the speaker driver. A sketch of that VSM is shown in Fig. 1. For simplicity and convenience, operation in a conventional electromagnet required vibrating of the sample perpendicular to the applied magnetic field. It was not obvious at first, but general principles were developed for arrangements of even numbers of pickup coils to detect

FIG. 1. First model of vibrating sample magnetometer (after Ref. 2).

the ac fields produced by the vibrating transverse moment while making the signal insensitive to sample position, vibration amplitude, and external field fluctuations to high order. Although generally inductive detection is used, any sensitive field sensor can be used; improved signal sensitivity can be expected for large transfer functions. Hall probes, magnetoresistors, and SQUIDs are largely frequency independent, whereas the inductive probe output is proportional to frequency. The symmetry arguments apply to all field sensors.

There were many new condensed matter physics problems to explore, and inexpensive war-surplus microwave equipment was available. These components were used for ferromagnetic, paramagnetic, and cyclotron microwave resonance programs pursued by the group. Field modulation combined with lock-in amplification was used routinely for signal processing. The lock-in amplifiers, originally developed at the Radiation Laboratory, were built in-house—no commercial instruments were available until the 1960s. The obvious way to enhance the signal-to-noise ratio of the VSM was to employ a lock-in amplifier, so I built one. The resulting simple magnetometer appeared to satisfy the requirements of convenience, versatility, and sensitivity and eliminated many of the shortcomings of other approaches. The first description of this VSM appeared in a short note² following one on megagauss pulsed field magnets,³ another project for which I volunteered. Five-hundred reprints of this VSM note disappeared in a few months (copying machines were not ubiquitous then) and I received approval from MIT to patent the VSM, but at my expense. My wife was then in medical school, so we justified the expense as further education for me; the patenting process was indeed educational. I have continued to use both the VSM and high fields for

FIG. 2. Mechanical details of VSM (after Ref. 5).

research (not discussed here). The development of high-field magnets, the Francis Bitter National Magnet Laboratory (FBNML), and high-field superconductors are reviewed in a recent publication.⁴

Magnetism was fashionable in the US then and there were many practical magnetic devices developed. Visitors came to Lincoln Laboratory to see the operating VSM and to get more details. I was spending too much time repeating myself, so I wrote a detailed article⁵ on the VSM that discussed the working model, Fig. 2. This led to further interest and 1000 reprints were exhausted in a short period. In the early 1960s I moved to the FBNML. There was a meeting in Boston at which Princeton Applied Research Corp. (PAR), at that time a startup instrument company, displayed a commercial lock-in amplifier (the JB-4) and I bought some for the Laboratory with the written proviso that they must meet the advertised specifications (they did). Later, when I inquired whether units could be purchased in quantity as an OEM product, I was invited to meet with the management to discuss the application. It is a long story, but I ended up assigning an exclusive license for the basic patent⁶ to PAR so that they could develop and market the VSM. Several related VSM patents have been issued.⁷ The commercial instrument continued to be produced by PAR (later as a subsidiary of

EG&G, Inc.) and recently the production was bought by LakeShore Cryotronics, Inc. The term VSM and Foner magnetometer have become somewhat generic in the literature, the original papers are rarely referenced, the VSM has been accepted as an ASTM Standard for magnetic measurements, the 1959 paper is cited as a Citation Classic,⁸ and now several companies produce various forms of VSMs. Papers continue to appear with modifications and rediscoveries; some are improvements, and some take a step backward. (Commercial VSMs are not immune to this syndrome.) The availability of inexpensive digital computers, automation, and packaged systems has made measurements much less tedious, but there still is no substitute for understanding the limitations of the systems. New names such as torque VSM, vector VSM, and biaxial VSM have appeared recently to describe the ability to detect the vector component of the magnetization (not in the field direction) discussed earlier.⁵ These are used, for example, for thin-film studies. Recently, some commercial SQUID instruments have added a VSM option.

The magnetic properties of a material are detected as a change in (1) magnetic flux, (2) force, or (3) by indirect techniques.⁹ Space limitations do not permit a discussion here of the many magnetic moment measurement techniques. An excellent treatment of many methods is given by Zilstra.¹⁰ Recent reviews are given in Refs. 11 and 12, where additional references are given. Here, I restrict my discussion largely to VSMs which use magnetic flux detection.

Almost all flux detection methods depend on the powerful benefits of sample motion to discriminate against contributions of the background flux. This includes the commercially available SQUID magnetometers, VSMs, and flux extraction; even ac susceptometers can take advantage of the moving sample principle. Moving the sample selects which part of the field distortion is due to the sample and also imparts externally controlled frequency, amplitude, and phase (wave form) information.

If a small sample is vibrated at a frequency f in a suitable detection coil array, the induced voltage E is given by

$$E = \sigma G A 2\pi f \cos 2\pi f t, \quad (1)$$

where σ is the magnetic moment of the sample, G depends on the detection coil geometry, and A is the (small) amplitude of the sinusoidal vibration. A reference signal is generated by an element on the drive rod (attached to an electro-permanent magnet or vibrating capacitor, etc.) which has the same amplitude and phase as the sample. If ratios of reference and sample signal are null-detected at the sensor input (the preferred mode), to first order, the null balance is independent of changes in A , f , amplifier gain or linearity, wave form, magnetoresistance of the detector coils, and small magnetic field instabilities. Otherwise these variables must be carefully controlled. E is made insensitive to position by choosing appropriate pickup coil configurations. The electronics acts as an ac bridge null detector. The first commercial instrument replaced the inductive reference sensor by a vibrating capacitor in the feedback balance arrangement.

The moving sample technique requires a well-designed

FIG. 3. Some examples of VSM coil configurations for vibration perpendicular to moment (after Ref. 13).

drive mechanism. The electromagnetic transducer is driven far from resonance. This permits changing the loading on the drive rod without affecting the response appreciably. Dynamic out-of-phase damping and shock mounting minimizes transfer of momentum to the VSM support. A single washer, e.g., V in Fig. 2, serves as a centering element and sliding bearing; note that two sliding bearings would overspecify the mechanical arrangement leading to unwanted binding and noise. A convenient means for sample change is desirable.

Practical detection coil arrangements for the VSM involve an even number of coils (or other detecting elements) in order to minimize sensitivity to sample position; for a dipole the signal varies as d^3 where d is the distance from the dipole. For the magnetization transverse to the vibration direction, no signal at frequency f is detected for coils with axes along the x , y , or z axis, for the coordinate system origin centered at the sample. Some examples of typical transverse detection coil configurations¹³ are shown in Fig. 3 and the appropriate positions of the vibrating sample are indicated. Figure 3(a) shows a two-coil arrangement^{2,3} and Fig. 3(b) shows a four-coil system by Mallinson.¹⁴ For either coil arrangement, components of \mathbf{M} along the y axis are obtained by either adding sets of coils rotated 90° about z , or by physically rotating the coils sets 90° about z . The eight-coil system by Bowden,¹⁵ Fig. 3(c), intercepts components of \mathbf{M} in the x , y , and z directions so that combinations of these coils can be used to detect the vector components of \mathbf{M} along these axes. Similar results can be obtained by rotating the 8-coil set 90° (Bernards *et al.*¹⁶), and a 12-coil set was discussed by Bernards and Cramer.¹⁷ The output is insensitive to position to first order because of symmetry for the sample centered as shown. Detection coil geometries and sensitivity functions (that give the proportionality constant for the magnetometer output of a unit dipole moment) are discussed by Zieba and Foner,¹³ and Pacyna and Ruebenauer.¹⁸ Sample geometry effects depend on relative sample size, given in terms of characteristic sample dimension versus coil radius. Calculations of these effects and experimental verification are given in Ref. 13 (see also special cases in Refs. 19 and 20) along with discussions of sensitivity and signal-to-noise of various coil configurations, sample position errors, sample support contributions, and related topics. The output for transverse moment detection coil systems cannot be calculated in closed form. Outputs of coil arrangements with axes along the vibration axis can be calculated in closed form, and these are employed for VSMs in axial fields produced by superconducting or other solenoids, where the moment is parallel to the vibration axis. However, for many studies an electromagnet using the transverse configuration is the best choice.

II. VERY LOW FREQUENCY VIBRATING SAMPLE MAGNETOMETER (VLFVSM)

In the mid-1960s Richard Frankel, now at California Polytechnic State University, was measuring the Pauli paramagnetism at high magnetic fields in Fe by the Mössbauer effect. I volunteered that we should be able to do much better with a VSM. Little did I know that it would be one of the most difficult experiments I had faced. The simplest approach was to use flux integration. The measurement involved detection of a very small change of a large quantity in the presence of field-dependent forces on the sample at high field in water-cooled magnets. High relative differential sensitivity was required, so that usually negligible systematic and instrumental errors became important. Richard Bozorth was experimenting at the Laboratory then and on hearing of our work decided to attempt this measurement. Of course, I told him that he was welcome to go first. Initially he used a galvanometer which was strongly affected by the fringe field of the magnets, so we furnished an integrating digital fluxmeter (a relatively new device at that time) that was insensitive to the fringing field. Bozorth adopted this device, but eventually decided to complete the work in a superconducting magnet.

Ed McNiff and I then returned to this problem. The solution came by indirection. My wife and I took a break at a local beach one weekend (a rare occurrence for us) and a simple solution occurred to me. Since it was not practical to position the sample sufficiently accurately in the pickup coils, the alternative was to avoid the issue; instead, move the sample beyond the centers of the coils and retrospectively determine where the centers were. We built a large-amplitude oscillating device which varied the frequency and amplitude of the sample displacement in the pickup coils and this became the heart of the VLFVSM.²¹ In order to measure small differences of the large integrated signal at fixed field, most of the output was precisely subtracted and only the expanded difference was displayed on a strip-chart record. The time drift of the integrator was also averaged. (This mode of operation, where the sample is moved past the centers of the flux detection coils and retrospectively analyzed, now is used in many SQUID magnetometers.) The VLFVSM is actually a rugged differential low frequency *flux-integration* device. This device could be set up in any magnet and was used at FBNML for magnetization measurements in high fields for about 20 years. The first serious test of the VLFVSM involved measurement of the high-field susceptibility of Fe and Ni.

The results of the Fe and Ni measurements were reported by both groups at a session of the M³ in 1965. We agreed to meet the previous evening to compare results; our experimental results differed. This was an interesting, lively, and very civilized get together; here I developed a great respect for Conyers Herring. These were difficult experiments and there were many possible sources of systematic errors. The theorists, Conyers Herring²² then at AT&T Bell Laboratories and Arthur Freeman,²³ now at Northwestern University, presented the results for the respective groups, each with an appropriate model. A detailed paper that also discussed the possible sources of systematic errors was published

subsequently.²⁴ More recently, René Pauthenet, in an invited paper at the 1981 M³ Conference,²⁵ presented extensive high-field susceptibility data to 18 T (using water-cooled magnets and flux integration with a digital integrating fluxmeter) for Fe, Co, Ni, and YIG. His data for Fe and Ni were in good agreement with Ref. 24.

III. VSM MODIFICATIONS AND COMMENTS

The remainder of this paper discusses selected examples of modifications made to VSMs for special needs. Although most involve the axial configuration for high-field work, they can be adapted for the transverse mode. These illustrate the ease with which the VSM can be modified. Many commercial systems can be changed to suit specific needs, often with little effort, e.g., adding or replacing the detection coils. Our modified (commercial) VSMs have flexibility built in. All the drive rods are sectioned and connectors are installed so that various length drive rods can be added and interchanged. This allows us to use a magnetometer at several magnet stations with different geometries. A small moveable, variable-speed overhead hoist allows removal and replacement of the heavy drive head from the magnet, so that the VSM can be used at several locations. The bottom section of the commercial drive rod that supports the sample is replaced by components that minimize background contributions. (Many commercial sample holders have quite large masses that are satisfactory for large ferromagnetic moments, but contribute large backgrounds to small moment samples.) We also use relatively large access spaces for the pickup coils for general work. These coil arrangements can be replaced by more efficient ones for higher sensitivity, but despite the fact that most of our research involves nonferromagnetic materials, the added sensitivity is rarely needed. Our helium Dewars for superconducting magnets are all relatively short, only about 30 in. long so that the conventional ceiling clearance is adequate when removing the VSM. Magnets are chosen for minimum usable bores so they are inexpensive and economical to run—a 6 T magnet uses 3 ℓ /day of He and 5–6 ℓ for the first fill. Finally, the pickup coils, clamped to the inner bore, are interchangeable. The modifications for specific needs discussed below are clearly illustrated in detailed figures of the quoted references, but are not reproduced here because of space limitations.

A. Operation at ³He

Some literature questioned whether the VSM could operate at ³He temperatures because of the heat generated; the vibration amplitude is generally about 0.1–0.2 mm. Oliveira²⁶ demonstrated VSM operation down to 0.5 K with a modification of the tail section to support a small Dewar for the ³He and a small surrounding ⁴He Dewar. Both are inserted in the central bore in a superconducting magnet containing the axial coil form. Many other experiments also require thermal isolation with a minimal loss of working volume. This is particularly important because the sensitivity is a strong function of detection coil dimensions. In order to satisfy these needs small pumpable space-saving Dewars with a simple valve seal²⁷ are used, adding as little as 0.75 mm in radius.

B. High pressures

In order to measure magnetic properties under high hydrostatic pressures, Guertin²⁸ used a modification of the VSM in a superconducting magnet where a hydrostatic pressure clamp, containing the small sample and pressure calibrator (Sn), was attached to the bottom section of the drive rod. The clamp had about 500 times the moment of the sample, but its contribution was reduced by a factor of 200 because of its geometry in the pickup coils. These small, pure Be-Cu clamps produced hydrostatic pressures up to $P \approx 8$ kbar. By replacing the bottom section of the sheath with a space-saver Dewar and accommodating a slightly smaller diameter clamp, measurements were made in a controlled variable-temperature environment under pressure and in high fields.²⁹ The first axial vibrating coil magnetometer was developed by Smith³⁰ in order to measure magnetic properties in a pressure bomb.

C. Very low frequency ac susceptibility VSM

A novel adaptation of the VSM was used for measuring the very low frequency ($0.003 < f_0 < 0.03$ Hz $\ll f$) ac susceptibility, χ_{ac} , of spin-glass PrP_y by Guyot *et al.*³¹ A small ac field was applied to the sample; the output of the VSM, which yielded the instantaneous response of M versus applied field, was recorded so that both the real and imaginary components of χ_{ac} were obtained. Of course lower values f_0 can be used with added patience.

D. Water-cooled and hybrid magnets

Early adaptation of the VSM to the high-power water-cooled magnets was examined and the electronics and mechanical components were modified by Hernan Pradde and Ed McNiff. The VSM driving frequency was returned to minimize detection of the 6 Hz and harmonics from the dc generators, and the drive rod and the surrounding sheath was extended so that the electromechanical drive head was not exposed to high fields (e.g., drive rod lengths were extended to ≈ 5 ft for water-cooled magnets and 8 ft for the 31.8 T hybrid). The PAR drive operates far from resonance and the drive power was adequate despite the added load. Yaacov Shapira, now at Tufts University, was examining the magnetization steps in dilute magnetic semiconductors which occur at very high fields and low temperatures.³² These measurements perform magnetic spectroscopy of the quantum mechanical level crossings, in, for example, antiferromagnetically coupled clusters.³³ The earliest magnetization step data³⁴ was obtained with the VLFVSM, but the point-by-point data taking was very time consuming for limited magnet time. (The data analysis was also time consuming, but that was off-line.) For more rapid data taking and for higher resolution, the VSM was the obvious choice so Shapira and McNiff installed the VSM as a Laboratory facility. For flexibility and good signal-to-noise, the axial pickup coils were mounted directly on the VSM sheath rather than clamped to the magnet. A three-coil axial arrangement (related to second-derivative coils) was used to minimize local field fluctuations. The standard VSM operated from 1.2 to 300 K. For operation down to 0.6 K, the bottom of the sheath including the pickup coils was immersed in liquid ³He of a

surrounding small space-saver Dewar arrangement. This VSM has been used for almost all the dc high-field magnetization measurements at FBNML for the last decade.

E. VSM operation at mK

A noteworthy recent adaptation extended VSM measurements to very low temperatures. Recently, plastic dilution refrigerators (PDR) have been developed that eliminate eddy current heating and allow operation in the mK range³⁵ in changing magnetic fields. The light weight and compactness of the PDR allowed demonstration of a practical VSM in that temperature range. The entire PDR tail section was attached to the drive rod and head of a commercial VSM vibrating at 82.7 Hz! With a dissipation < 100 μ W, operation below 50 mK was reported.³⁶

F. SQUID VSM magnetometer

A SQUID (Superconducting Quantum Interference Device) magnetometer is a type of VLFVSM that incorporates a SQUID detector and electronics instead of a conventional integrating circuit. The SQUID generally operates at 4.2 K and is an extremely sensitive flux detector which must be carefully shielded. It is adequate to consider a SQUID a "black box" with a very low input impedance and very low noise, a very wide frequency response starting at dc, and a large transfer function. It matches the low impedance input to the room-temperature electronics. The sample is moved through the detector coils (usually restricted to a few turns total, separated by a few cm) for either peak detection or fitting the flux variation versus displacement of the sample. The point-by-point operation suffers from the same limitation of the above VLFVSM; it is point-by-point and slow. Unlike the inductive detector VSM whose output is proportional to frequency, the output of the SQUID detector is independent of frequency. Recently SQUID systems have been incorporating a VSM option (operating at a few Hz) for continuous data.

G. Calibration

The most convenient method of calibration of a VSM (and many other magnetometers) is to use a small standard reference comparison sample. Ni measured above technical saturation is recommended because it has a high and well-known moment so that large signals are obtained for a small sample, it is chemically stable, has a low saturation field, is inexpensive, is readily available in high purity, and even at 300 K is only slightly temperature sensitive.

H. Image effects

The flux distribution produced by a sample is distorted by any highly permeable medium (ferromagnetic or superconducting) in its neighborhood so the detected signal is affected. This effect is called the image effect. Observations of image effects of VSMs in superconducting magnets are discussed by Zeiba and Foner.³⁷ The superconducting magnet image effects can be subtle, and are influenced by whether the magnet is operated in the persistent mode or not,³⁸ and how densely it is wound.³⁷ The effect depends on the detailed geometry, increasing rapidly and nonlinearly as the

detection coils approach the high permeability medium because then they intercept more of the distorted flux of the sample. However, if the VSM or other device is calibrated with a known test sample, this image effect automatically is eliminated to first order, because both the flux from calibration and measured samples are affected in the same way. However, the measured values will be affected by the *field dependence of the image effect*. Both ferromagnets and superconducting wire show some field-dependent shielding changes. Recently, Zeiba³⁹ has given an extensive review of image and geometry effects of superconducting shields, flux transformers, and magnets in SQUID magnetometers. It should be noted that there is an additional image effect for large signals due to the currents in the flux transformer circuit, when using the *average flux-nulling* feedback mode. This effect can be eliminated by using a *current-nulling* feedback mode.

IV. SENSITIVITY

Despite statements to the contrary, lack of sensitivity is rarely an issue for the VSM, particularly for the MMM audience, and it can easily be improved by modifying the pickup coils or other detector so that they more effectively couple to the sample as discussed earlier.⁴⁰ For the same reasons, comparisons of sensitivity of different systems must be done with care because small changes in coil geometry can produce widely different sensitivities. For the axial configuration, as the coupling is increased, the signal-to-noise increases as $r^{-7/2}$ if limited by Johnson noise of the wire, and as r^{-5} if limited by field noise, where r is the pickup coil radius. As a demonstration for small samples, a change of magnetic moment of 1×10^{-9} emu at 1 T and 3×10^{-9} emu at 5 T could be detected in a (nonpersistent-mode) superconducting magnet⁴⁰ with the small detection coils clamped onto the VSM assembly.

Although not the purpose of this paper, I mention a few early M³ memorable to me: (1) the second M³ in Boston that took place in 1956; (2) the 1959 M³, when the program committee rejected a paper by S. Autler as not relevant (it discussed use of superconductors in electromagnets and was the start of the first revolution in high-field superconductors, cf. Ref. 4, p. 123.); (3) the first evening symposium on magnetic measurement techniques,⁹ chaired by R. M. Bozorth,⁴¹ at the 1966 M³ (the overflow audience was moved to the largest lecture hall; such symposia occur at intervals now); and (4) the first joint M³ and International Conference of Magnetism in Boston in 1967. Of note was the evening champagne party at the Isabella Stewart Gardner Museum in Boston where antiphonal brass rang out across the balconies of this imported Italian villa. Several subsequent M³ hosted evenings in local museums.

My experience was that each time I volunteered it led to new and interesting areas of activity for me and long-term dividends. Along the way I was fortunate to be involved in many areas and collaborations with many scientists and engineers; the list is too long to enumerate here. I wish to thank my many co-workers who made these enterprises so rewarding. The work at the Francis Bitter National Magnet Laboratory was funded by the National Science Foundation.

Measurement of texture in magnetic recording media using a biaxial vibrating sample magnetometer

F. Schmidlin, P. R. Bissell, and J. A. Gotaas

*Department of Physics and Astronomy, University of Central Lancashire,
Preston PR1 2HE, United Kingdom*

A method is described for the determination of the three dimensional easy axis distribution in recording media using a biaxial vibrating sample magnetometer and compensation for out-of-plane demagnetization field effects. Comparison of Lorentzian function fits to the data and measurement of orientation ratio with theoretical calculations indicates that the method gives a reasonable measure of the easy axis distribution. Examination of the theoretical relationship indicates that low values of orientation ratio are insensitive to distribution width indicating that it is necessary to make a full measure of easy axis distribution in-plane. However, out-of-plane distributions are generally narrower and it is often possible to estimate distribution width from a simple orientation ratio measurement. © 1996 American Institute of Physics. [S0021-8979(96)79708-4]

I. INTRODUCTION

Orientation of magnetic particles in recording media has a major effect on magnetic properties and media recording performance. This is normally assessed by means of parameters such as squareness, orientation ratio (OR) and S^* . Although this gives an indication of the maintained properties and quality of a particular medium during production or development, it does have severe limitations and does not take into account the out-of-plane characteristics of media texture. In some advanced recording, the out-of-plane component can have a very important role in the properties and needs to be included in the media characterization. For example, metal evaporated tape has an inclined columnar structure which determines the structure of written bits; a longitudinal barium ferrite media can have an out-of-plane component which affects erasure properties. Furthermore, with the development of sophisticated micromagnetic models and their use to predict and interpret media behavior, full knowledge of the three dimensional easy axis distribution (EAD) is required. In this article we describe a technique which we have developed to measure the in-plane and out-of-plane distribution of easy axes in recording media using a biaxial vibrating sample magnetometer (VSM). Because the technique compensates for demagnetizing fields during measurement and gives a direct evaluation of the texture, it is equally applicable to any media irrespective of the texture axis direction or asymmetry in the distribution. However, in this article we concentrate on longitudinal particulate media.

The measurement may take considerable time (up to one day of automated measurement to obtain one out-of-plane EAD) and is therefore not suitable for routine characterization of media. However, curve fitting techniques are applicable to standard longitudinal media and our measurement technique can be used to assess the effectiveness of these fits and the suitability of the functions chosen.

II. METHOD

Techniques to determine the EAD in recording media have been described which use either torque¹ or VSM measurements.^{2,3} It is assumed that when a large saturating

field is applied at angle φ to the recording direction it will switch particle or grain moments so that, when returned to the remanent state, they occupy their easy axis directions closest to the field direction. If the field direction is now rotated to an angle $\varphi + \delta\varphi$ and the field application and removal repeated, the change in the vector remanence will be the result of moment switching for grains with easy axis directions between $\varphi + 90^\circ$ and $\varphi + \delta\varphi + 90^\circ$.¹ By repeating the measurement process for different values of φ from 0° to 180° , the easy axis distribution can be obtained in that plane of measurement.

We have extended the technique to out-of-plane measurements by using a biaxial VSM which allows for measurement of the sample magnetic moment to be made in the field direction and orthogonal to it with the ability to rotate the sample during the measurement process. A large magnetic field is applied to the sample at a particular direction and removed to leave the sample in a remanent state. This process can be used for in-plane and out-of-plane measurements although this step is more complex when out-of-plane. This is because the internal field must be kept in its original direction within the sample as the field is reduced to zero if a valid remanent state is to be created. Thus, for out-of-plane measurements, as the field is reduced constant calculation of the sample magnetization and rotation of the sample to adjust the internal field (applied plus demagnetizing) direction is required.⁴

By repeating in-plane and out-of-plane measurements, a full three dimensional description of the medium texture can be obtained which does not resort to function fitting, a technique⁵ often used for media with longitudinal anisotropy but not applicable to tilted media.

The limitation of the technique is that out-of-plane measurements take considerable time even with a computer controlled VSM and it is necessary to use procedures to reduce the measurement time to a level which is acceptable for laboratory media characterization. The major difficulty is in maintaining the internal field, H_i , in a given direction, while reducing it from saturation to zero. For example, reducing the applied field, H_a , may cause the magnetization, $I(H_i)$, to decrease and rotate through a small angle. This in turn affects

FIG. 1. In- and out-of-plane easy axis distribution for the $\gamma\text{-Fe}_2\text{O}_3$ sample.

the demagnetizing field, H_d , and hence the value and direction of H_i . If these changes are too large, irreversible switching of some moments may occur, invalidating the final remanent state. Thus, the measurement routine has to proceed cautiously, trying to predict what changes will occur in the magnetization strength and direction and to compensate for them.

To increase the speed of our EAD measurements, we assume that the sample response to field removal in two directions separated by a small angle will be similar. If we have mapped one such curve, we can use it to predict the second curve and select appropriate step sizes and angular rotations during the measurement. Additional adjustments are then made to correct for the small differences.

III. RESULTS AND DISCUSSION

Here we describe the use of our technique to measure three conventional longitudinal media: a CrO_2 hand spread, a $\gamma\text{-Fe}_2\text{O}_3$ audio tape and a Metal Particle Hi8 tape. These have been selected because they exhibit a range of different textures. It is essential to know true magnetization, rather than the magnetic moment usually measured by conventional

FIG. 2. In- and out-of-plane easy axis distribution for the CrO_2 sample.

FIG. 3. In- and out-of-plane easy axis distribution for the metal particle sample.

VSM techniques, in order to calculate H_d . This was determined using the technique developed by Sollis *et al.*⁶ which relies on the shift in the transverse susceptibility (χ_t) anisotropy peak produced by H_d when measurements are made out-of-plane.

Measured easy axis distributions in-plane and out-of-plane are shown in Figs. 1–3. It has to be stressed that the technique provides a direct measurement of the EAD. However, for analysis purposes the resulting easy axis distributions were fitted by a Lorentzian function

$$y = ab^2/(x^2 + b^2), \quad (1)$$

where a is a normalizing factor and b gives the width of the distribution. The fits are shown with the data in Figs. 1–3. The choice of function follows the work of Templeton *et al.* who found it to be a good fit to longitudinal in-plane easy axis distributions,³ with a tail out to 90° . It can be seen that in general the out-of-plane distribution is narrower than the in-plane which is not unexpected in particulate media given the coating process of production. Table I gives the measured widths of the fitted functions along with orientation ratios in and out-of-plane for the three samples.

The EAD width can be linked to the orientation ratio. Assuming a distribution $f(\alpha)$ about the mean easy axis ($\alpha=0$) and normalized to saturation, the squareness [$Sq = I(0)/I(\infty)$] measured at an angle θ to the average easy axis will be the sum of all the moment components along θ so that:

TABLE I. Sample characteristics.

	I_s (kA/m)	OR in plane	b in- plane (deg)	OR out of plane	b out-of- plane (deg)
$\gamma\text{-Fe}_2\text{O}_3$	70	1.5	32.1	2.9	12.3
CrO_2	107	3.0	19.8	4.0	12.6
MP	274	2.1	21.0	2.9	13.7

FIG. 4. Comparison between measured EAD width (b) and values calculated from the orientation ratio.

$$Sq(\theta) = \int_{\theta-\pi/2}^{\pi/2} f(\alpha) \cos(\alpha - \theta) d\alpha + \int_{\pi/2}^{\pi/2+\theta} f(\alpha + \pi) \cos(\alpha - \theta) d\alpha. \quad (2)$$

OR is defined as $Sq(0)/Sq(\pi/2)$ so that the variation of OR can be calculated for different distribution widths, b , for a Lorentzian distribution. The calculated theoretical relationship is shown as a continuous line in Fig. 4. Data points are experimental measurements of OR and distribution widths for the three samples. Within an acceptable experimental error, data points lie close to the theoretical curve and indicate that the method of demagnetization field correction and curve fitting to the data gives a reasonable measure of the easy axis distribution.

Perhaps one of the most significant features of the theoretical curve is the insensitivity of the OR to the distribution width, b , for broad distributions. For values greater than $b \approx 20$, OR declines very slowly relative to the increase in b . This indicates that for wide distributions, OR is not an effective measure of the EAD. However, as OR increases it can be used to predict distribution widths more accurately. Since most in-plane orientation ratios of conventional longitudinal

media fall into the low OR category, easy axis distributions can only be assessed accurately by a full measurement. However, since the OR is generally higher when measured out-of-plane, its use to assess the EAD in that direction is likely to be more accurate. Since the out-of-plane measurement is the one which is time consuming with its demagnetization corrections, it appears that a satisfactory assessment of the three dimensional easy axis distribution can be obtained for most longitudinal media by an EAD measurement in-plane and an OR determination out-of-plane. Since both these measurements can be made on a conventional VSM, although less conveniently than on a bidirection instrument, full 3D EAD characterization is possible in most measurement laboratories. However, each sample must be considered on its own merits and the applicability of the determination judged with reference to the curve in Fig. 4.

IV. CONCLUSION

We have demonstrated that it is possible to measure the easy axis distribution of recording media both in-plane and out-of-plane with a bidirectional VSM using demagnetization field compensation for out-of-plane measurements. However, the method is very lengthy and not suitable for normal magnetic characterization of media. A comparison of curve fits to experimental data and orientation ratio determination shows that, although OR is not sensitive to the width of the easy axis distribution for low OR values, it is capable of predicting distribution widths for narrow distributions. Since out-of-plane EADs are narrower than those in-plane, in some cases a satisfactory estimation of the 3D EAD can be obtained from a full EAD determination in-plane and an OR measurement out-of-plane. We emphasize that the applicability to each sample must be judged with respect to the theoretical curve of Fig. 4.

Application of Barkhausen effect measurements for detection of near surface stress (abstract)

D. A. Kaminski and D. C. Jiles

Center for NDE, Iowa State University, Iowa

Barkhausen effect emissions have been shown to be dependent on stress in previous work.¹ This paper shows how the technique has been applied to evaluation of stress in automobile crankshafts. These components often fail prematurely due to residual tensile stress in the surface of the components, which leads to cracking and sudden fatigue failure. The measurements were made using an excitation frequency of 8 or 128 Hz with signal detection bandwidths of 3–15, 20–70, and 70–200 kHz. These corresponded to nominal magnetic field penetrations of 0.2, 0.07, and 0.02 mm. Results showed that measurements from the near surface (0.02 mm) were most sensitive to stress. A number of calibration experiments on different materials confirmed this result. In addition, it was found that low values of the root-mean-square Barkhausen voltage correlated with low tensile strength of the material. This measurement could, therefore, be used for detection of components that were likely to encounter early failure. A calibration of the Barkhausen voltage signal as a function of stress was obtained and this was in accordance with earlier theoretical calculations.² © 1996 American Institute of Physics. Nondestructive inspection of a fractured nickel bar by Barkhausen and magnetoacoustic emissions

C. C. Yu, C-D. Qin, and D. H. L. Ng^{a)}

Department of Physics, The Chinese University of Hong Kong, Shatin, Hong Kong

Barkhausen emission (BE) and magnetoacoustic emission (MAE) measurements have been made on a nickel bar before and after it is torn apart by a tensile stress. The BE and MAE profiles obtained are all single-peaked. The peaks obtained after fracture are found at the lower field regions of the profiles, and this suggests that the field required for the domain wall motion in the fractured bar has been lowered. In the BE measurement, the signals show an increase of 44% (away from fracture end) to 144% (at fracture end); on the contrary, the MAE signals show a reduction of 43% (away from fracture end) to 14% (at fracture end). As the nickel bar is fractured, we find that in the broken pieces, the grains have been elongated in the stressed direction, and there is an increase of defects such as dislocations, voids and microcracks, especially near the fracture end of the bar. BE which is sensitive to these factors, has therefore been intensified. On the other hand, the plastically elongated grains, which have a lower absolute magnetostriction, enhance the reduction of MAE activity. The results measured from the nickel bar will be compared with those obtained from a fractured mild steel bar, which has different magnetostriction and other magnetic properties.

© 1996 American Institute of Physics. [S0021-8979(96)50608-3]

I. INTRODUCTION

Barkhausen emission (BE) is the induced signal in the induction coil due to the change of magnetic flux in the magnetic sample, while magnetoacoustic emission (MAE) is the acoustic wave emitted when there is a change of magnetostrictive strain.¹ Both BE and MAE have been under development as techniques for the nondestructive evaluation of magnetic materials.² The possibilities of measuring stress,³ detecting defects⁴ and measuring sample thickness⁵ have already been demonstrated. A practical application of BE and MAE to estimate the degree of damage in steel components have previously been reported.⁶ In this article, we report both BE and MAE measurements taken from two different positions of a broken piece of a nickel bar resulting from a tensile loading. Our purpose is to find the dependence of the BE and MAE signals on the microstructures of the bar, which are observed as being different from one region to another. We have also compared the results with those reported from the previous study of a broken mild steel bar,⁶ aimed at improving the understanding of the physical mechanism of the BE and MAE from fractured components of the two materials with similar metallic characteristics, but with different magnetic properties.

II. EXPERIMENTS

A nickel bar of dimensions 190 mm × 20 mm × 4 mm was annealed at 900°C before it was torn apart by a 300 kN Instron loading machine. The stress applied to break the bar was about 257 MPa. A 1 Hz magnetizing field of triangular wave form and peak-to-peak magnitude of 90 kA/m was produced by a *c*-core electromagnet. The field was applied parallel to the strained direction during the BE and MAE measurements. A flat induction coil placed underneath the *c*-core electromagnet was used to detect the BE signals from the

surface of the sample, while the MAE signals were picked up by a nearby piezoelectric transducer. Both BE and MAE signals were amplified, rectified and filtered before they were plotted over half a hysteresis cycle. The BE and MAE measurements were taken at two positions of the broken bar, one near the fracture end, and the other one is 5 cm from the fracture end. The signals obtained were compared with those of the original bar. Hardness tests and optical microscopy were also performed at these two positions of the bar before and after it was fractured in order to measure the changes of the mechanical hardness and the microstructure of the bar.

III. RESULTS

The BE and MAE profiles of the original nickel bar are shown in Figs. 1(a) and 1(d) respectively, while the profiles obtained near the fracture end of one of the broken pieces of the bar are shown in Fig. 1(b) for BE, and Fig. 1(e) for MAE. At 5 cm away from the fracture end, the BE and MAE profiles obtained are shown in Figs. 1(c) and 1(f) respectively. The result shows that after the bar is torn, there is an overall increase of BE signals, but a reduction of MAE signals. The increase of BE is 144% at the fracture end and 44% away from the fracture end, while the reduction of MAE is 14% and 43% at these two positions. A summary of the BE and MAE signals normalized to the signals obtained from the original bar are shown in Table I. Results obtained from the optical microscopy show that the average diameter of the grains of the original bar before fractured is ~ 60 μm, and the ratio of its long axis to the short axis, *y/x*, is about 1. In the hardness measurement, the Vicker's test is used as reference, the Vicker's hardness number (VHN) of the bar is 101. Such a number indicates that the bar is relatively soft, and we have therefore observed significant necking as the bar is strained beyond its elastic limit. The strain at break is measured to be 36%. After the bar is torn, the value of *y/x* and the VHN near the fracture end are measured, and are equal to 3 and 170 respectively. While, at the region 5 cm from the

^{a)}Electronic mail: B108771@vax.csc.cuhk.hk

FIG. 1. BE profiles (a, b and c) and MAE profiles (d, e and f) as a function of an applied field H_a . Profiles a and d are obtained from the original nickel bar; profiles b and e are obtained from the broken bar with measurements made near the fracture end while profiles c and f are obtained at a position 5 cm from the fracture end. Both horizontal and vertical axes are of the same arbitrary scale for each profile.

fracture end, the value of y/x and the VHN are 2 and 154 respectively. These results are also tabulated in Table I.

IV. DISCUSSION

A. Barkhausen emission

As the nickel bar is torn, some of the major mechanical changes are: (i) numerous defects such as dislocations, microcracks and voids are created in the broken pieces of the bar, (ii) the grains are elongated in the strained direction, and (iii) the cross sectional area of the bar is no longer uniform. The first change is indicated by the increase of the VHN. The dislocations become less mobile as they are hindered by the defects created during the fracture, thus the VHN increases and indicates that the broken bar is hardened. This effect however does not reduce the mobility of the domain walls. We observed that the peaks of the BE profiles as well as the MAE profiles obtained from the broken bar are found at the lower field regions [Figs. 1(b) and 1(e)], this suggests that the field required for the motion of domain walls has been lowered. The facts that the dislocations formed during fracture are mostly lying perpendicular to the stressed direction

and the field that applied to the bar is parallel to the stressed direction, as long as the walls are intersecting at some angle to the dislocations, the pinning effect is minimal and the domain wall motion has not been affected.⁷ The optical microscopy reveals the elongation of the grains, which is another consequence of the fracture. The increase of the length of the grains in the y direction facilitate the domain wall motion as the magnetizing field is applied parallel to the strained axis, therefore the rate of change of magnetic induction, dB/dt , increases, thus a higher BE at the lower field region has been detected. Finally, the change of the cross sectional area of the bar can be easily observed by direct measurement. As the bar is strained, there has been a decrease of cross sectional area of the bar particularly at the necked region near the fracture boundary. Such a reduction has led to an increase of flux density inside the broken bar, and the BE signal which is proportional to dB/dt , has intensified accordingly.

We also observe that the largest increase of the BE signal is found near the fracture end. This variation of BE signals along the broken bar is due to the facts that the existence of relatively larger numbers of dislocations and microcracks, the most severe elongation of grains, and the smallest cross sectional area, are found at this region of the bar. All these factors contribute to the large BE response.

B. Magnetoacoustic emission

In contrast with the BE measurement of the fractured bar, the MAE activities decrease after the bar has been torn. One of the main factors leading to the overall reduction of the MAE signals is the decrease of the absolute magnetostriction of the elongated grains. In the presence of a tensile stress, the crystal lattice will be elongated in the stressed direction, nickel with a negative magnetostriction will have a smaller absolute strain.⁸ Therefore after fracture, the nickel bar which has been plastically deformed, would have a smaller absolute magnetostriction. As the MAE activity is proportional to the magnitude of magnetostrictive strain, we have therefore observed that the MAE of the broken bar has decreased. At the same time, there are still some factors that would tend to enhance the MAE signals, which are the same as those that enhance the BE signals, such as the increase of flux density in the smaller cross section and the elongation of grains. However these factors appear not strong enough to make compensation for the overall loss of MAE activity due to the lowering of the absolute magnetostriction, nevertheless they are much more effectual at the position near the fracture end when compared with the situation at the far end. As a consequence, the reduction of MAE activity near the fracture end is less. It is also known that the closure domains which are mainly confined by the non-180° domain walls, always reside on grain boundaries, microcracks and voids, therefore the total area of the non-180° domain wall would increase as the defect density of the sample increases resulted from fracture. Since the MAE is generated by the motion of the non-180° domain wall, as a result MAE is relatively stronger in the fracture end where there are more non-180° walls. This also supports the fact that the decrease of MAE near the fracture end is smaller.

TABLE I. The peak values of BE and MAE normalized to the values obtained from the original nickel bar, VHN and y/x ratio measured from the bar before and after fractured, at positions near and 5 cm away from the fracture end.

		BE	MAE	VHN	y/x
Before		1.00	1.00	101	1/1
Fractured					
Fractured	Near	2.44	0.86	170	3/1
	Away	1.44	0.57	154	2/1

C. Comparison of nickel and mild steel

In the BE and MAE measurements of steel,⁹ the profiles of both emissions usually contain two outer peaks, the initial peak represents domain wall nucleation while the final one is due to annihilation. This phenomena also applied to the situation in a fractured steel bar as we had reported in our earlier work.⁶ However, in the BE and MAE profiles of the fractured nickel bar, a single peak is found at the low field region, which is a contribution of the domain wall motion. The fact that the central peaks do not appear in the BE and MAE profiles of mild steel but in nickel only, can be explained by the difference in the mobility of the domain walls in steel and nickel. It is known that the velocity of the wall is inversely proportional to the spontaneous magnetization M_s ,¹⁰ therefore in a material with a lower M_s , such as nickel, the domain wall would be more mobile than that in steel. The existence of the strong central peak in the nickel profile confirms that the domain wall is easily unpinned in the low field. While in steel, the BE and the MAE activities contributed by the wall motion require a higher field, and is in the vicinity of where the annihilation process occurs, thus the two processes are superimposed into the final peak, and therefore only two outer peaks are found in the mild steel profiles.

Also in the mild steel results, the enormous increase of BE after the bar was fractured has also been reported. The above mentioned reasons used to explain the increase of BE in the nickel bar after fracture are also applicable to account for the mild steel case. However, the percentage increase of the BE signal in steel is 240%, and that in nickel is 144%. In order to explain the large difference, we consider the fact that in steel the rate of change of magnetization, dM/dt which is equal to $M_{\max} f$, is larger than that of nickel, where M_{\max} is the maximum magnetization at the maximum applied field and f is the frequency of the magnetizing field of triangular wave form. In the MAE measurement obtained from the fractured steel bar, a reduction of 10% at the fracture end was reported, whereas 14% reduction is reported for the nickel bar. As the steel bar is hard and brittle, the elongation of the grains in the fracture bar is a lot smaller than that in the nickel bar which is more ductile.

Although the mechanical strain in the grain of steel is small, it still possesses a significant effect on the MAE signal due to the lowering of the absolute magnetostriction. This

effect on steel has the same order of influence on nickel although nickel has a larger magnetostriction, it is because the mechanical strain in the grain of nickel is large. Therefore, there should not be a great difference in the amount of MAE reduction in the two fracture bars.

V. CONCLUSIONS

Significant changes occur in BE and MAE activities after tensile stress of rupture strength is applied on a nickel bar. From the study of the peak values of both signals at the fracture end and the far end of the broken nickel bar, we find that BE activity is intensified while MAE activity is suppressed. The changes of both BE and MAE activities are strongly related to the presence of defects and dislocations, the change of microstructures and the alternation of the physical dimensions of the broken bar. Employing these two techniques, we can realize the presence of stresses, structural defects and the relative values of dislocation and defect densities. A tremendous jump in BE signal indicates that the nickel component is severely damaged and plastically deformed. This can be reconfirmed by a slight decrease in MAE signal. With reference to both measurements, nondestructive investigation of nickel would be much more reliable.

A two-dimensional single sheet tester incorporating controlled magnetization direction

J. J. Dalton, J. Liu, A. J. Moses, D. H. Horrocks, and A. Basak
Cardiff School of Engineering, UWCC, Cardiff CF2 1XH, Wales, United Kingdom

The existence of magnetic anisotropy in electrical steels has long been known to designers of electrical machines. However the effect of this anisotropy in real devices has not to date been studied in any great depth. Finite element modeling software is proving useful for designing such electrical machines, however, the material models which form the heart of the process are based on limited data and indeed often make incorrect assumptions regarding the anisotropic nature of the machine core. This article discusses shortcomings of present anisotropic material models, suggests what is needed to overcome these shortcomings and presents one such two-dimensional magnetic test system capable of generating the materials data required. The method by which the data is obtained is described and measured results are presented, indicating some of the features of the system. © 1996 American Institute of Physics. [S0021-8979(96)50708-X]

INTRODUCTION

The area of modeling of anisotropic electrical steels is receiving much attention presently. Grain oriented 3% silicon iron exhibits a high degree of anisotropy when magnetized out of its prominent rolling direction plane. This material is widely used as the core in power transformers and due to this magnetic anisotropy constitutes a source of large energy losses.¹

Finite element modeling (FEM) techniques are increasingly being used as a design and analysis tool for electromagnetic machines. This numerical approach has as its nucleus a material model which is taken to characterize the magnetic properties of the material from which the electromagnetic core being designed is assembled. However these models suffer from several shortcomings which the system presented here attempts to overcome.

PROBLEMS OF CONVENTIONAL MAGNETIC ANISOTROPY MODELS

Conventional anisotropy models are based on one-dimensional $B-H$ relationships of the form

$$B_x = f_x(H_x), \quad B_y = f_y(H_y). \quad (1)$$

That is, the flux density component in the X or rolling direction is a function only of the field in the X direction. Similarly for the Y or transverse components. It can be easily shown that the approach given in Eq. (1) can be improved (ignoring a z component) by employing the following approach:

$$B_x = f_x(H_x, H_y), \quad B_y = f_y(H_x, H_y). \quad (2)$$

In order to construct the $B-H$ relationship shown in Eq. (1) or Eq. (2), the measured $B-H$ data from anisotropic magnetic materials is required. Conventional anisotropic models are formed from two measured $B-H$ curves (rolling and transverse directions), while using certain kinds of interpolation techniques to obtain intermediate curves.² These two measured $B-H$ curves do not reflect the full magnetic ma-

terial behavior, especially when the direction of magnetization is away from the measured $B-H$ directions as happens in real machines.³

Generally for magnetic materials the $B-H$ constitutive relation can be stated as

$$\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{M}. \quad (3)$$

It is seen that vector \mathbf{B} is the resultant of the magnetization vector \mathbf{M} and field vector \mathbf{H} . Depending on magnetization conditions it is therefore possible for the vectors \mathbf{B} and \mathbf{H} to be separate in space. This angle between \mathbf{B} and \mathbf{H} in practical cases creates regions of higher power losses in devices and so merits investigation.

The constitutive relation given in Eq. (3) is a one-dimensional relation, however it can be extended to yield a two-dimensional tensor relation. This tensor relation shows the mutual interlinking of the X and Y magnetizing directions. It is clear that to produce a more accurate model, the material data should reflect this dependence. What is in fact needed is measured $B-H$ data at intermediate magnetization angles. This data should include B - and H -total magnitude information as well as the instantaneous angular information of B and H total.

CONTROLLED DIRECTIONAL MAGNETIZATION SYSTEM

The magnetization system presented here is shown in Fig. 1 and is based on an orthogonal yoke arrangement for two-dimensional magnetization of electrical steel sheets 300 × 300 mm in dimensions. The flux density (B_x, B_y) components and the field intensity (H_x, H_y) components are obtained via B and H (calibrated) coils wound through, and on top of the sample, respectively. The excitation wave form generation and the sensor output signal analysis are all achieved by using a novel virtual instrumentation technique.⁴ All the signal processing functions such as integration, filtering, spectral analysis, wave form analysis/reconstruction etc. are performed using software modules constructed within this environment.

On application of a magnetizing current to the rolling direction winding it is observed that besides the expected H_x

FIG. 1. The presented two-dimensional magnetizing system used showing excitation and measurement techniques.

component there exists a field in the transverse direction (H_y), and vice versa as reported by Nakata *et al.*⁵ These H_x and H_y , and correspondingly B_x and B_y , components can be said to be "coupled" and thus the setting of a particular flux density at a given angle cannot be achieved simply by application of independent excitation waveforms to the X and Y excitation coils. These excitation waveforms must be generated according to measured B_x and B_y for the required magnetization conditions.

To achieve the required setting of the flux density components, an algorithm was developed which was based on the minimizing of the following objective function:

$$f = (B_{xm} - B_{xref})^2 + (B_{ym} - B_{yref})^2, \quad (4)$$

where B_{xm} is the measured value of B_x and B_{xref} is the reference or desired value of B_x . Similarly for B_y . The reference values of B_x and B_y are calculated from

$$\begin{aligned} B_x &= B_t \cos \theta_B, \\ B_y &= B_t \sin \theta_B, \end{aligned} \quad (5)$$

where B_t represents the total flux density component, that is

$$B_t = \sqrt{B_x^2 + B_y^2}. \quad (6)$$

The minimization function given in Eq. (4) was used as the controlling function for the direction setting algorithm. The minimization was performed as a sequential series of linear X and Y scans. Each scan involves stepping the output to either the X or Y excitation coil (whichever scan is being performed) while the output to the other coil is maintained constant. For each step the B_x and B_y signals are measured instantaneously and compared with the reference values B_{xref} , B_{yref} for the required point and angle. After each X or Y scan the point (voltage input to the excitation coil windings, see Fig. 1) causing the function f to be a minimum is recorded and used as the constant input for the following scan. The ranges of both X and Y scans are cut or fine tuned

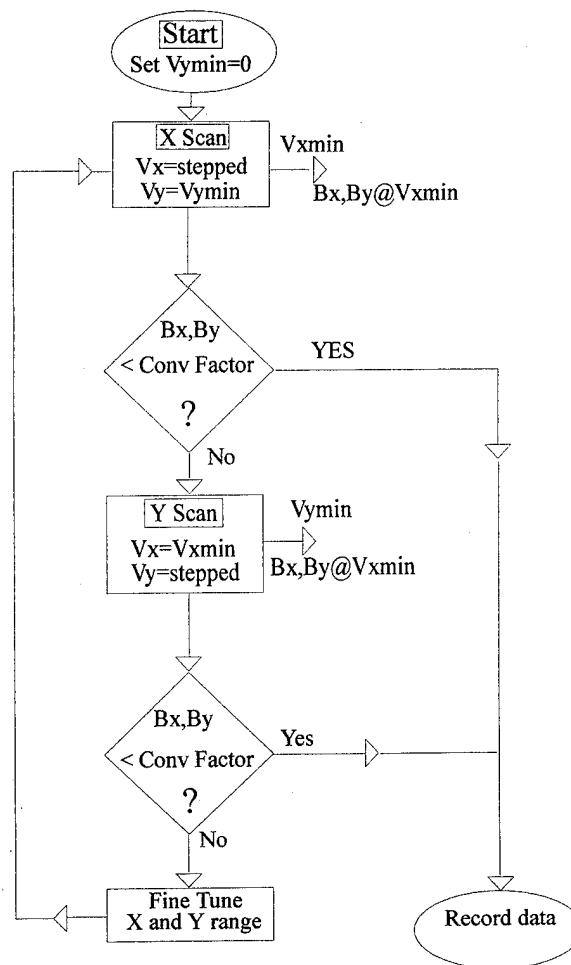

FIG. 2. Flowchart of objective function minimization scanning algorithm.

consecutively around the minimum points obtained from the scans, in a grid-reduction fashion. The process is equivalent to a two-dimensional surface scanning procedure which is based on distance minimization. The flowchart in Fig. 2 details the sequence.

This consecutive X and Y scanning is repeated in an iterative manner until the function f is found to be within a particular range of a designated accuracy number (convergence factor) for the required flux density and angle. This convergence factor is a number designating how small f should become before the required accuracy has been reached. When this convergence has been reached data can be recorded.

Due to the nonlinearity of the material the flux density in the sample was found to be highly distorted. For this reason the selection of the wave form instant on which to take the instantaneous component values is quite important to ensure stability of the scanning routine.

To this end it is desirable to have a monotonic decrease and increase up to and after a minimal point, respectively. This ideal response is shown in Fig. 3, which corresponds to a flux density of 0.5 T at 30° to the rolling direction of a sample of grain oriented silicon iron. Ripples on this response are to be avoided as the possibility of missing the

FIG. 3. The objective function change is plotted against scan steps for 30°, 0.5 T. This is an ideal response of f as it ensures algorithm stability.

required point and converging around the wrong point then becomes a reality. The four wave forms B_x, B_y, H_x, H_y were all instantaneously sampled at $|H_{\text{totalpeak}}|$ as it was found that this instant offered most stability in terms of the convergence routine. Note $|H_{\text{totalpeak}}| = \sqrt{H_x^2 + H_y^2}$. The voltage inputs v_x and v_y to the excitation coils were uncontrolled in shape as reported previously.⁶

RESULTS AND DISCUSSION

The system was tested for various magnetization angles between 0° and 90°. The complete flux and field wave forms were recorded and the instantaneous angular information was recorded.

Figure 4 shows a typical $B-H$ curve for a sheet of 27 M4 grain oriented silicon and also the instantaneous H angular information for a magnetization angle fixed at 30° with respect to the rolling direction. It is seen that for lower flux density levels (<1.0 T), the H angle is close to 90°, while at higher flux densities (>1.0 T) the H angle drops steadily and eventually settles at around 56°–57°. This is significant as it shows that the measured results do not tie in with what the

FIG. 4. A typical $B-H$ curve for a magnetization direction of 30° is shown. Also included is the H angular information.

FIG. 5. The flux density set by the system is plotted against reference or ideal values at various angles (dotted lines).

assumed results would have predicted. Figure 5 plots system accuracy for various magnetization angles in terms of angular accuracy. The accuracy was found to be in the range 97% for magnitude accuracy and 95% for angular accuracy, however due to high levels of flux wave form distortion, there was a practical upper limit to the level of flux density achievable at particular angles. These problems presented themselves worst between 40° and 60°, reflecting the anisotropic hard axis. This problem presently limits the system as to the maximum flux density it can achieve for any particular angle. However it is known⁷ from early work that the flux density in real devices never reach these high levels anyway so in many ways, from a design point of view, it is not really necessary to have information for these higher levels. From a general knowledge point of view of course it is desirable to have this information and so it is an objective of the authors to pursue this. These experimental results will be reported later.

CONCLUSION

A two-dimensional magnetic test system capable of magnetizing at user defined angles was successfully constructed. This information takes previous work a step further and allows the user to set up his own magnetization conditions based on flux density control. The complete B and H magnitude and angular information is now obtainable for any user defined magnetization angles thus facilitating us to take the anisotropic modeling process one step further.

A magnetoelastic torque transducer utilizing a ring divided into two oppositely polarized circumferential regions

I. J. Garshelis and C. R. Conto

Magnetoelastic Devices, Incorporated, P.O. Box 625, Pittsfield, Massachusetts 01202

Significant improvements in both transducer performance and constructional simplicity is achieved by dividing a single ring into two equal width regions having oppositely directed circumferential magnetizations. The square hysteresis loop associated with the uniaxial anisotropy in the ring enables this magnetization arrangement to be readily instilled by rotating the shaft/ring assembly in the dipole fields of a set of axially separated permanent magnets having opposing polarizations. Following the removal of the magnets, each such region effectively becomes a single domain separated from the other only by a centrally located 180° domain wall. Unchanging performance of the transducer throughout nearly 10^7 torque cycles, severe overloads, and a wide range of thermal environments attest to the stability of both the remanent magnetizations in each region and the position of the domain wall. © 1996 American Institute of Physics. [S0021-8979(96)50808-6]

INTRODUCTION

We have previously described¹ a noncontact transducer wherein the torque carried by a shaft is indicated by the polarity and intensity of a magnetic field arising from a rigidly attached ring of circumferentially polarized, magnetostrictive material. We subsequently described² a transducer construction utilizing two contiguous rings having oppositely directed circumferential polarizations and showed that with this arrangement, ambiguous contributions to the torque responsive field, from ambient magnetic fields, could be effectively eliminated. It was clear from the analysis that this important improvement does not rely on the presence of two physically distinct rings, but derives instead from the difference in the responses of their respective magnetizations to torsional stress and to magnetostatic fields. Thus it is to be expected, and indeed it was suggested,² that a single ring, divided into two oppositely magnetized regions separated only by an encircling 180° domain wall, should mimic the performance of the two rings, at the same time providing a physically simpler construction.

Unlike the case with two separate rings wherein each ring can be readily magnetized in the desired circumferential direction by a coaxial current pulse prior to its assembly onto the shaft, the establishment of two oppositely polarized regions within a single ring clearly requires a different approach. In this article we show a simple means for simultaneously magnetizing two such regions and demonstrate that the resulting polarizations and location of the domain wall are stable over a wide range of environmental and operating

conditions. Such stability is clearly crucial to the utility of the resulting torque transducer.

DESCRIPTION

Figure 1 shows the assembly of elements comprising a complete torque transducer. The ring, of magnetostrictive material, exhibits by its shape and typically also by a tensile "hoop" stress associated with its interference fit on the shaft, an effectively uniaxial magnetic anisotropy, K_u , having its easy axis in the circumferential direction. The ring is divided into two equal width regions, A and B, distinguished only by the opposite circumferential directions of their remanent magnetizations M_{rA} and M_{rB} . Because of the square $M-H$ loop associated with K_u , these remanent magnetizations approximate the saturation magnetization, M_s . The shaded transition region between A and B has no significant width; it is effectively a 180° domain wall encircling the ring and may in fact attain the structure and dimensions of an actual domain wall. Other than in these different details of magnetization and a few related consequences (to be discussed), operation of the device shown in Fig. 1 as a torque transducer follows the detailed description and analysis given in previous works.^{1,2} Attention here is to the means of attaining the distinctly bordered, oppositely magnetized regions in a single ring.

FIG. 1. Elements comprising the torque transducer. FS is field sensor.

FIG. 2. Geometric considerations for determining the field, H_{easy} from a magnet of dipole strength m at any point P on the ring.

FIG. 3. Calculated easy axis field around ring for various magnet gaps.

PRINCIPLES OF MAGNETIZATION METHOD

While it is possible to use axial currents to polarize the two regions with the ring already in place on the shaft, magnetization by rotation through the fields from an antiparallel set of permanent magnets is a more practical method, allowing the same simple apparatus to be used with a wide range of shaft and ring sizes. The principles of this magnetizing method can be readily understood by considering first the action of the field from a *small* permanent magnet on a single region of the ring as the shaft is rotated on its axis. The location and orientation of the magnet, considered here as a simple dipole of moment m , relative to the ring are indicated in Fig. 2. The magnet is spaced from a thin (negligible radial thickness) ring of radius R by air gap G . The field H at any point P in the ring, distance r from the tangentially oriented dipole is readily found from³

$$H = \frac{m}{r^3} (3 \cos^2 \theta + 1)^{1/2}, \quad (1)$$

where θ is the angle between m and the r vector. For any position angle α , r is found (from the Law of Cosines) as

$$r = [(R+G)^2 + R^2 - 2(R+G)R \cos \alpha]^{1/2}. \quad (2)$$

H is seen to be directed at angle ϕ to r , where³ $2 \tan \phi = \tan \theta$.

With a small enough magnet, HM_s is at all points $< K_u$, hence only the tangential component of H , i.e., H_{easy} , can have any irreversible effects on the local direction of ring magnetization. From the geometry in Fig. 2 it is seen that,

$$H_{\text{easy}} = H \cos(\alpha - \theta - \phi). \quad (3)$$

The variations of H_{easy} with α , as found from Eqs. (1) to (3), are plotted in Fig. 3 (as percentages of their maximum

FIG. 4. Circumferential distribution of ring magnetization. (a) After full revolution. (b) Transiently, following magnet removal. (c) After polarity reversal within minor sector by fields at sector boundaries.

FIG. 5. Determination of H_c by disappearance of torque induced field.

values) for three values of G . In all three plots, H_{easy} is seen to cross zero (i.e., reverse direction) at relatively small angles on either side of $\alpha=0$, although these zero crossing angles are seen to depend significantly on G . The normalized peak reverse fields however, are seen to be notably insensitive to G , being always near 20% of the maximum H_{easy} .

If the shaft (ring) is now rotated (in either direction) for at least one full revolution, and if G and m are such that the peak negative value of $H_{\text{easy}} > H_c$ (the coercive force), all portions of the ring not situated in positive fields $> H_c$ will become magnetized in the negative direction, since such is the polarity of that field greater than H_c to which they were last exposed. The distribution of magnetization within the ring after such rotation (also while rotating) is shown in Fig. 4(a). If the field from the magnet is then sufficiently reduced (e.g., by insertion of a high permeability shield or "keeper" between the magnet and the ring) as to effectively eliminate the magnet's presence, the magnetization within the ring will relax to the distribution shown in Fig. 4(b). If the combined intensity of the demagnetizing field from the minor sector of the ring and the field acting on it from the major sector exceeds H_c , the magnetization within the minor sector will be reversed, thereby leaving the entire circumference of the ring magnetized in a single circular direction as shown in Fig. 4(c).

It should be clear that the field from m also extends axially and that, subject to the requirement that the peak negative values of $H_{\text{easy}} > H_c$, even a stationary magnet can polarize a ring wider than itself. Thus it should also be clear that, used in the manner described, a fixed array of two axially separated, oppositely polarized magnets of equal

FIG. 6. Magnet arrangement used to simultaneously polarize two regions.

FIG. 7. Circumferential variations in easy axis field of actual magnet.

FIG. 9. Variation of radial field from 10 N m torque with position.

strengths will simultaneously create two regions on the same ring having antiparallel remanent magnetizations.

EXPERIMENT

The ring/shaft assembly used in this study was already described² in a previous work wherein the ring was uniformly magnetized over its entire 20 mm width in a single circular direction. Measurements were performed that provided a novel means of determining H_c of the ring *in situ*. Since operation as a torque transducer is based on the appearance of a field due to the torque induced tilting of an originally circumferential remanent magnetization, M_r , the polarity and magnitude of the field arising from the application of a fixed torque can be used to indicate the direction and relative magnitude of M_r . Thus when $M_r=0$, no field arises with torque. The experiment consisted of measuring the radial field near one end of the ring with an applied torque of 10 Nm following the passage, axially through the shaft (with zero torque), of successively larger currents having reversed polarity circular fields. The resulting data are plotted in Fig. 5.

The sharp critical field at 2.2 Oe reflects the expected dominant uniaxial anisotropy. The imperfect verticality of the subsequent reversal of M_r is also expected considering the finite thickness of the ring and the dependence of the internal circular field on radius. H_c is readily identified as 2.4 Oe. The somewhat sluggish approach to saturation (requiring

nearly 7 Oe to reach 99.3%) is attributed to the gradual growth in hoop stress (hence, K_u) inward from the ends of the ring due to internal chamfers.

Two region polarization was accomplished by rotation in the fields of a proximate pair of bonded ferrite magnets,⁴ sized and positioned as shown in Fig. 6. H_{easy} was found to vary with axial position along these magnets, reaching symmetrical maxima 7 mm from the axial centerline. Measured values of H_{easy} at one such location, around a 17 mm diam. circle, with the edge of the magnets 10.7 mm from the center are plotted as a percentage of the maximum value (110.8 Oe) in Fig. 7. The close resemblance of this plot to the Gap=0.5 R curve in Fig. 3 is especially striking in view of the areal distribution of dipoles in the actual magnets. The peak reverse fields, occurring at $\alpha=\pm 32^\circ$, are seen to also approximate 20%. The variation of peak reverse field with axial position is plotted in Fig. 8. The transition zone between regions within which the reverse easy axis field exceeds H_c is seen to be ≈ 1 mm. While the status of magnetization and actual width of this zone are presently unknown it clearly acts effectively as a 180° domain wall.

Measured values along the ring of the radial component of the field arising with the application of a 10 N m torque to the shaft are plotted in Fig. 9. The variation in field is seen, as expected, to follow the form associated with an axial quadrupole, moderately modified by the demagnetizing effects of each region on the other. No significant variation in data of this kind was found after heating to 150°C , cooling to -50°C , each for several hours, immersion in liquid N_2 , and more than 9×10^6 cycles of reversing torque. This attests to the stability of both the remanent magnetizations and the position of the wall separating them.

FIG. 8. Variation of peak reverse field with axial position.

DISCUSSION

Comparison of Fig. 9 with Fig. 5 in Ref. 2 shows that the single ring, two region construction provides a higher sensitivity (field per unit torque) than with two separate rings, attributable to the greater M_r attainable by magnetization *after* installation of the ring on the shaft.

Hall-effect characterization in semiconductor heterostructure junctions using polarized laser signal

Hoton How and Ta-Ming Fang

Massachusetts Technological Laboratory, Belmont, Massachusetts 02178

Feng Lu and Brian Ahern

RL/ERXE, Rome Lab., Hanscom AFB, Massachusetts 01731

We describe a new technique which exploits the ac Hall effect in the characterization of layered semiconductor structures. The method employs laser signals in the presence of a dc magnetic bias field. Upon incidence the polarization of the optical signal is rotated via a Lorentz force due to the ac Hall effect. As such, the reflected waves carry information on the Hall mobility of the charge carriers. The calculations show that ac Hall reflection warrants sufficient intensity to be measured. Our theory is complete in the sense that depth profiling has been explicitly incorporated in the formulation. © 1996 American Institute of Physics. [S0021-8979(96)50908-X]

INTRODUCTION

Materials for present-day high-speed devices, such as high electron mobility transistors, often have many conducting layers incorporating semiconductor heterostructure junctions.¹ The straightforward dc Hall-effect techniques can be of only very limited use to analyze such materials. The problem is that the standard dc Hall-effect method measures only two parameters, resistivity ρ and Hall coefficient R_H , and thus is able to determine only two unknowns, the carrier concentration n and mobility μ , in a single layer. Extra information might be obtainable by measuring the magnetic-field dependencies of ρ and R_H upon which n and μ can be indirectly estimated for a two-layered structure.² Shortcomings for the current dc Hall-effect measurements are that they are not able to profile or characterize a semiconductor sample either horizontally or vertically. The present theory of the dc Hall effect always assumes limiting cases, adopting either the so-called two-band or the two-layer models.³ In reality, space charges can accumulate/deplete across the sample layer boundaries depending on the relative strength of their respective electrochemical potentials. A new technique is presented in this paper which is able to provide local characterization of layered semiconductor samples. The technique exploits an ac Hall effect using laser signals in the presence of a dc bias magnetic field. The ac currents induced by the laser signal will experience a Lorentz force which deflects the electron/hole motion in the semiconductor, resulting in polarization rotation of the incident radiation. Therefore, by measuring the cross-polarized signals in the reflected and/or the transmitted optical beams, an ac Hall effect can be suitably characterized. Since no dc Hall voltage is measured, the method can be applied locally, with the scale limited only by the size of the incident laser beam. Most importantly, depth profiling of the semiconductor sample can be incorporated in this new technique. Since an electromagnetic wave propagates sequentially across the layers, the overall effect can be formulated provided that the respective parameters associated with each of the layers are known *a priori*. The predicted effects are of sufficient magnitude to warrant experimental interest.

FORMULATION

Analogous to the derivation of the gyromagnetic permeability, we first derive an expression for the tensor permittivity of a semiconductor medium in the presence of a dc bias magnetic field subject to Drude damping as⁴

$$\epsilon = \epsilon_\infty \mathbf{1} - \frac{j}{\omega} \boldsymbol{\rho}^{-1}, \quad (1)$$

where

$$\boldsymbol{\rho} = \begin{pmatrix} \rho(1+j\omega\tau) & -R_H B & 0 \\ R_H B & \rho(1+j\omega\tau) & 0 \\ 0 & 0 & \rho(1+j\omega\tau) \end{pmatrix}.$$

ϵ_∞ , after dividing by ϵ_0 , the permittivity of vacuum, denotes the (optical) dielectric constant of the medium, and τ is the damping time constant. Electric resistivity and Hall coefficient are

$$\rho = -q(\mu_n n + \mu_p p)^{-1}, \quad R_H = -r q p^2 (\mu_p^2 p - \mu_n^2 n),$$

μ_p and μ_n are the mobilities, and p and n the concentrations for holes and electrons, respectively. The thermal statistic factor is absorbed in the parameter r which is defined as $r = \langle \tau^2 \rangle / \langle \tau \rangle^2$, where $\langle A \rangle$ denotes the statistic average of quantity A over all the possible electronic states. For degenerate bands, $r = 1$. Note that μ_p and μ_n may contain contributions from both processes arising from phonon and ionized impurity scattering.

Let the semiconductor structure consist of n layers. The zeroth and the $(n+1)$ -th layers are both semi-infinite located above and below the semiconductor structure which can be the air or the substrate. The dc magnetic field is applied normal to the layered structure and the ac (optical) signal is considered to propagate along the magnetic-field direction (normal incidence), denoted as the z axis. The permittivity tensor can be diagonalized in terms of circularly polarized waves as

$$\epsilon^\pm = \epsilon_\infty + \frac{j}{\omega} \frac{1}{\rho(1+j\omega\tau)} \left(1 \pm \frac{j R_H B}{\rho(1+j\omega\tau)} \right)^{-1}. \quad (2)$$

Denote the permittivities of the i th layer as ϵ_i^\pm , $1 \leq i \leq n$, which can be evaluated from Eq. (2) by using the respective parameters of the layer, including resistivity, carrier concentration, and mobility, etc. The thickness of the i th layer is d_i , $1 \leq i \leq n$. The electromagnetic fields at the two sides of the layered structure can be related by a total transfer matrix⁴

$$\mathbf{T}^{\pm, \text{tot}} = \prod_{i=1}^n \mathbf{T}^{\pm, i}(d_i) = \begin{pmatrix} a^\pm & b^\pm Z_0 \\ c^\pm & d^\pm \end{pmatrix}, \quad (3)$$

such that

$$\begin{pmatrix} e_s^\pm \\ h_s^\pm \end{pmatrix} = \mathbf{T}^{\pm, \text{tot}} \begin{pmatrix} e_0^\pm \\ h_0^\pm \end{pmatrix}. \quad (4)$$

Here the individual transfer matrix for each layer is⁴

$$\mathbf{T}^{\pm, i}(d_i) = \begin{pmatrix} \cos k_i^\pm d_i & -jZ_i^\pm \sin k_i^\pm d_i \\ -\frac{j}{Z_i^\pm} \sin k_i^\pm d_i & \cos k_i^\pm d_i \end{pmatrix}, \quad (5)$$

$$k_i^\pm = \sqrt{\mu \epsilon_i^\pm} \omega \quad \text{and} \quad Z_i^\pm = \sqrt{\frac{\mu}{\epsilon_i^\pm}},$$

and superscript $+$ ($-$) denotes right-hand (left-hand) polarization. We also have used subscript $i=0(s)$ to refer to the layer of air (substrate). The overall reflection and transmission coefficients of the structure are, respectively,⁴

$$r^\pm = \frac{-(a^\pm + b^\pm)Z_0 + (c^\pm + d^\pm)Z_s^\pm}{(a^\pm - b^\pm)Z_0 - (c^\pm - d^\pm)Z_s^\pm}, \quad (6)$$

$$t^\pm = \frac{2(a^\pm d^\pm - b^\pm c^\pm)Z_s^\pm}{(a^\pm - b^\pm)Z_0 - (c^\pm - d^\pm)Z_s^\pm}. \quad (7)$$

Therefore, when the incident beam is polarized in the x direction, the reflected and transmitted beams in the cross-polarized (y) direction are

$$r_{\text{ac-Hall}} = j(r^+ - r^-)/2, \quad t_{\text{ac-Hall}} = -j(t^+ - t^-)/2. \quad (8)$$

The overall transfer matrices can be written in the form of Eq. (3) only if surface currents are absent from the layer boundaries. As such, the tangential magnetic fields vary continuously across the boundaries. If surface currents do exist, the above transfer matrix theory cannot be directly employed. Rather, the current sheet itself shall be treated as a separate semiconductor layer whose thickness is vanishingly small. That is, for a two-dimensional current sheet (2-DEG) one assumes d goes to zero. Thus n (or p) goes to infinity, with the product of d and n (or p) being finite. This results in finite surface carrier concentrations and finite surface resistance of the current sheet, denoted as n_s and R_s , respectively. As such, the transfer matrix associated with a 2-DEG sheet takes the following form:

$$\mathbf{T}^{\pm, 2\text{-DEG}} = \begin{pmatrix} 1 & 0 \\ -[R_s(1 \mp r\mu_n B)]^{-1} & 1 \end{pmatrix}, \quad (9)$$

which can be then used in Eq. (3) for calculating $\mathbf{T}^{\pm, \text{tot}}$.

FIG. 1. The ac Hall reflection as a function of frequency.

RESULTS

We consider in this paper the calculation of the ac Hall reflection by a five-layered semiconductor heterostructural junction. The first layer is the cap material made of n^+ -GaAs with carrier concentration 10^{18} cm^{-3} for ohmic contact purposes. The second layer is n -AlGaAs, which provides electrons to form a quasi-two-dimensional Fermi gas near the AlGaAs-GaAs interface. The dopant level here is 10^{18} cm^{-3} . However, due to electron diffusion into the 2-DEG sheet, the electron concentration in the second layer is about an order smaller than the dopant level (10^{17} cm^{-3}).² The third layer is an undoped AlGaAs layer, which serves as a spacer to separate the accumulated electrons in the 2-DEG sheet from their parent donor impurities in the second layer to enhance electron mobility. The fourth layer is the 2-DEG sheet whose default values in carrier concentration and mobility are 10^{12} cm^{-2} and $10\,000 \text{ cm}^2/\text{V s}$, respectively. The fifth layer is the undoped GaAs material, which, due to its high electron affinity, attracts electrons from the n^+ -AlGaAs layer to form the 2-DEG sheet. We consider the electron mobility to be $1000 \text{ cm}^2/\text{V s}$ for the AlGaAs materials and $4000 \text{ cm}^2/\text{V s}$ for the GaAs materials. The carrier concentration for the undoped materials (AlGaAs and GaAs) is 10^{14} cm^{-3} . The thicknesses of these layers are, respectively, 500, 500, 20, 0, and 1000 \AA . We assume semi-insulating GaAs is used as the substrate, whose carrier concentration is 10^6 cm^{-3} and mobility is $1000 \text{ cm}^2/\text{V s}$. In the following calculations we consider the optical dielectric constant of GaAs and AlGaAs to be 10.9,⁵ which differs from their dc value of 12.79.⁵ The statistic factor r is taken to be 1, which corresponds to the degenerate case of the electronic states.

Figure 1 shows the ac Hall reflection for $\mu_{2\text{-DEG}} = 10\,000 \text{ cm}^2/\text{V s}$ and $B = 1 \text{ T}$. In Fig. 1 oscillations appear at high frequencies ($> 2 \times 10^{14} \text{ Hz}$), arising from internal reflections due to the layers' structural boundaries, say, the surface boundaries of the fifth layer of the undoped GaAs (thickness 1000 \AA). Similar results are also obtained for higher $\mu_{2\text{-DEG}}$ and B values, which shows higher reflection coefficients, indicating that the magnitudes of ac Hall reflection are in the range which warrants accurate measurements.⁴

FIG. 2. The ac Hall reflection as a function of magnetic field.

To be explicit, let us assume the ac signal is furnished by a Nd:YLF laser source providing light signals of wavelength $\lambda = 1.054 \mu\text{m}$ (for example, Quantronix 416). Figure 2 shows the calculated ac Hall reflection as a function of the applied magnetic field, B , for $\mu_{2\text{-DEG}} = 10\,000 \text{ cm}^2/\text{Vs}$. It is seen in Fig. 2 that maximum reflection occurs at $B = 1.194 \text{ T}$, with a value of -13.87 dB . Similar results are found for $\mu_{2\text{-DEG}} = 20\,000 \text{ cm}^2/\text{Vs}$, where the maximum occurs at $B = 0.929 \text{ T}$, with a value of -9.924 dB .⁴ Therefore, by searching for optimal magnetic bias producing maximum ac Hall reflection, the magnitude of $\mu_{2\text{-DEG}}$ can be deduced.

Figure 3 shows the calculated reflection as a function of electron density in the 2-DEG sheet, n_s , assuming $\mu_{2\text{-DEG}} = 10\,000 \text{ cm}^2/\text{Vs}$, $B = 1 \text{ T}$, and $\lambda = 1.054 \mu\text{m}$. We showed elsewhere that⁴ in Fig. 3 for $n_s > 7 \times 10^{10} \text{ cm}^{-2}$, ac Hall reflection is attributed to Hall rotation in the 2-DEG

FIG. 3. The ac Hall reflection as a function of surface carrier concentration.

sheet, identified as the larger (primary) peak in the reflection curve of Fig. 3. For $n_s < 7 \times 10^{10} \text{ cm}^{-2}$, reflection from the cap layer dominates, appearing as the smaller peak (secondary) in Fig. 3. The ac Hall reflection due to the other layers (layers 2, 3, 4, and substrate) is almost invisible in Fig. 3, indicating that the considered semiconductor structure is essentially a two-layered system producing Hall rotation. This is called parallel conduction as reported in the dc Hall measurements.^{2,3} Other properties of the layered structure are discussed in Ref. 4.

Using x-ray and polarized neutron (PNR) reflectivity, we have measured the structural and magnetic depth profiles of annealed $\text{Ni}_{80}\text{Fe}_{20}$ (20 Å)/Ag (40 Å) multilayers. The x-ray data indicate that the interfaces are highly mixed. PNR measurements of the 335 °C annealed multilayer in small magnetic fields reveal a broad feature in the off-specular spin-flip scattering that is not present for the unannealed sample. The giant magnetoresistance is thus associated with antiferromagnetic correlations between micrometer-sized magnetic domains within the $\text{Ni}_{80}\text{Fe}_{20}$ layers. This spin ordering is consistent with a model in which weak dipolar forces lead to an antiparallel alignment of the domains across the Ag layers. © 1996 American Institute of Physics. [S0021-8979(96)51008-4]

Sparked by the discovery of giant magnetoresistance (GMR),¹ studies of transition-metal multilayers have revealed complex correlations among their transport, magnetic, and structural properties. Neutron scattering has been important in determining the microscopic magnetic structure of these materials because one can obtain both the orientation and magnitude of the moment as a function of depth, independent of the sample volume. For example, Barthélémy *et al.*² used neutron techniques to prove that the peak in the resistivity for Fe/Cr multilayers is associated with antiparallel alignment of the ferromagnetic Fe layer moments. Subsequent diffraction studies³ confirmed the oscillatory dependence of the exchange coupling on the nonmagnetic interlayer thickness.

We have applied polarized neutron reflectivity (PNR) techniques to the study of sputtered $\text{Ni}_{80}\text{Fe}_{20}/\text{Ag}$ multilayers annealed at different temperatures. The as-grown multilayers show a change in resistivity $\Delta R/R_{\text{sat}} < 0.3\%$ independent of the Ag layer thickness, though a maximum magnetoresistance change of $\approx 5\%$ is obtained after annealing at temperatures near 335 °C.^{4,5} The measured saturation fields H_{sat} for the multilayers are smaller than 100 Oe, making them attractive candidates for magnetic sensor applications.

Cross-sectional transmission electron microscopy (XTEM) studies⁶ indicate that annealing promotes the formation of Ag "bridges" spanning the $\text{Ni}_{80}\text{Fe}_{20}$ layers. Off-specular x-ray data suggest that annealing also reduces the lateral disorder through the interfacial region.⁵ PNR measurements reveal that these structural modifications change the nature of the interlayer exchange coupling. Specifically, a broad peak at the half-order antiferromagnetic position is evident in transverse scans for the 335 °C annealed

multilayer. The induced GMR is thus associated with antiferromagnetic correlations between the $\text{Ni}_{80}\text{Fe}_{20}$ layer moments along the growth axis, but the in-plane domains are small ($\approx 1\text{--}5\text{ }\mu\text{m}$). In agreement with previous suggestions,^{4,7} we demonstrate that the strength of the field required to overcome the dipolar interaction between two finite plates is comparable to the saturation fields measured for the annealed samples.

For this study, four (111) textured multilayers of nominal composition $\text{Ta}(100\text{ Å})/\text{Ag}(20\text{ Å})/[\text{Ni}_{80}\text{Fe}_{20}(20\text{ Å})/\text{Ag}(40\text{ Å})]_4/\text{Ni}_{80}\text{Fe}_{20}(20\text{ Å})/\text{Ag}(20\text{ Å})/\text{Ta}(40\text{ Å})$ were sputtered onto silicon substrates under conditions described elsewhere.^{4,6} Following growth, three of the multilayers were annealed at 305, 315, and 335 °C, respectively. $\Delta R/R_{\text{sat}}$ and H_{sat} were obtained from bulk transport and magnetization measurements, and their dependence on anneal temperature follows that described in a related study.

Using a double-axis x-ray spectrometer, we examined the samples at small angles to characterize the structural changes induced by annealing. Following subtraction of the background, superlattice peaks are visible only out to second order, as illustrated in Fig. 1 which shows the specular reflectivity for all four multilayers. From fits of the x-ray data we conclude that the $\text{Ni}_{80}\text{Fe}_{20}$ and Ag layers are strongly mixed along the growth-axis direction. (Details of these x-ray fits will be published elsewhere.⁵) The growth-plane averaged scattering⁵ densities in the centers of the $\text{Ni}_{80}\text{Fe}_{20}$ and Ag layers differ by as much as 10% from their bulk values, indicating that Ag is present in the $\text{Ni}_{80}\text{Fe}_{20}$ layers (and vice versa) both prior to and after annealing. In Fig. 1 there is also a shift of the superlattice peaks to lower Q_z with increasing anneal temperature, suggesting that the bilayer thickness systematically increases. These data are not conclusive, however, because the bilayer spacings were not measured prior to annealing.

FIG. 1. Specular x-ray reflectivity of the $\text{Ni}_{80}\text{Fe}_{20}/\text{Ag}$ multilayers. The circles correspond to the data and the solid lines are fits. The superlattice peaks in (d) are masked by interference fringes from the oxidized Ta base and cap layers.

The effects of annealing are seen principally in transverse x-ray scans, which are sensitive to the in-plane interfacial structure. At small values of Q_z , the Q_x scans have two distinct components centered at $Q_x=0.0 \text{ \AA}^{-1}$: a resolution-limited specular peak atop a broad diffuse peak.⁵ The width of the diffuse component is inversely related to the coherence length ξ of the in-plane structural features. Crude estimates⁶ of ξ vary between 3.5 and 5.5 μm , which is characteristic of grain boundaries, interfacial terracing, or other microscopic inhomogeneities within the sample plane. At all of the Q_z values considered, the width of the diffuse peak for the as-deposited sample is broader than that for the 335 °C annealed sample. Apparently ξ increases with anneal temperature as the in-plane structural domains coalesce. Combining these results with those of specular reflectivity and XTEM,⁶ we propose that the Ag already present tends to conglomerate within the nominal $\text{Ni}_{80}\text{Fe}_{20}$ layers, possibly at the grain boundaries, and breaks the $\text{Ni}_{80}\text{Fe}_{20}$ into long, flat pancakes. This particulate structure seems to develop only in sputtered $\text{Ni}_{80}\text{Fe}_{20}/\text{Ag}$ multilayers. As-grown epitaxial permalloy/Ag multilayers show no evidence of grain boundaries, though annealing does act to smooth the in-plane structure and expel Ag from the $\text{Ni}_{80}\text{Fe}_{20}$ layers.¹⁰

To characterize the magnetic structure, we performed PNR studies at the NIST Research Reactor using both specular and off-specular scattering geometries. The former provides a measure of the vector magnetization profile as a function of depth if the in-plane domains are large ($\geq 50\text{--}100 \mu\text{m}$). Details of the in-plane magnetic order can be obtained from off-specular analysis. For both geometries, we mea-

sured all four spin cross sections, $(++)$, $(--)$, $(+-)$, and $(-+)$, as a function of field applied in-plane. (The $+$ and $-$ signs designate the parallel and antiparallel polarizations, respectively, of the incident and scattered neutrons relative to the applied field.) The $(++)$ and $(--)$ non-spin-flip data are sensitive to both the nuclear and magnetic structures, their difference being related to the in-plane component of the magnetization parallel to the applied field. The $(+-)$ and $(-+)$ spin-flip data sense only the component of the magnetization perpendicular to the field.

We measured the specular reflectivity of the 335 °C annealed multilayer at its coercive field value of -4 Oe to probe the spin structure of the demagnetized state. The scans show *no* magnetic scattering at either the half-order or first-order superlattice peak position that would be characteristic of a net antiferromagnetic or ferromagnetic alignment, respectively, of the $\text{Ni}_{80}\text{Fe}_{20}$ interlayers.⁵ The data for the as-deposited sample in a field of 0.6 Oe are similar. These featureless data imply that the ferromagnetic $\text{Ni}_{80}\text{Fe}_{20}$ layers order in discrete in-plane domains smaller than the coherence length of the incident neutrons ($50\text{--}100 \mu\text{m}$).

A picture of the magnetic structure emerges from transverse (Q_x) scans for the 335 °C annealed and as-deposited multilayers at Q_z values corresponding to the nominal half-order and first-order superlattice peak positions. Each sample was first studied in a saturation field of $H=250 \text{ Oe}$ and then in applied fields near their coercive values (-3.2 and -0.3 Oe , respectively), where the magnetoresistance is maximum. The data in Figs. 2(a)–2(d) are the difference between the low- and high-field spin-flip results, corrected for polarization efficiencies. A broad diffuse peak at $Q_x=0.0 \text{ \AA}^{-1}$ is seen at half-order [Fig. 2(a)] for the 335 °C annealed multilayer, while the corresponding scan at first order [Fig. 2(b)] is flat. These data imply that the GMR arises from the formation of small, ferromagnetic $\text{Ni}_{80}\text{Fe}_{20}$ domains within the sample plane. That the scattering appears only at half-order suggests that some portion of these domains is antiferromagnetically coupled along the growth-axis direction. The remaining spins align either in in-plane domains that are uncorrelated from one bilayer to the next or in in-plane domains smaller than our detection limit ($\approx 1000 \text{ \AA}$). From the full width at half-maximum of the diffuse spin-flip peak [Fig. 2(a)], we estimate an in-plane domain size of $1\text{--}5 \mu\text{m}$, which is the same order of magnitude as the structural correlation length ξ obtained with x rays.

In contrast, the spin-flip-scan at the half-order position for the as-deposited multilayer shows no significant scattering when the field is lowered to its coercive value [Fig. 2(c)]. The corresponding data at the first-order position deviate slightly from background near the scan center [Fig. 2(d)], probably due to leakage of non-spin-flip scattering. Clearly, the low-field magnetic structure of the as-deposited multilayer is different from that of the 335 °C annealed sample.

Both the bulk magnetization⁴ and PNR data for the as-deposited multilayer indicate that the coupling between the $\text{Ni}_{80}\text{Fe}_{20}$ layers is ferromagnetic. This coupling may be intrinsic or may result from the presence of $\text{Ni}_{80}\text{Fe}_{20}$ "pinholes" which connect the Ag layers.⁹ (Such a structure is

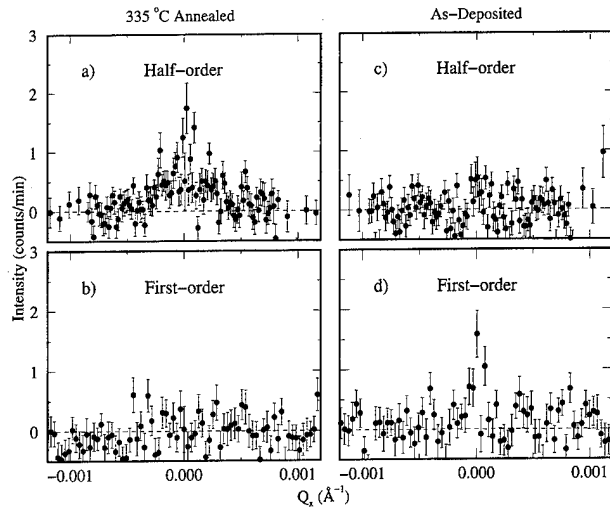

FIG. 2. Difference between neutron Q_x scans in fields of -3.2 and 250 Oe for the 335°C annealed multilayer (a) half-order ($Q_z=0.048\text{ \AA}^{-1}$) and (b) first-order ($Q_z=0.091\text{ \AA}^{-1}$). The difference between scans in fields of -0.3 and 250 Oe for the as-deposited multilayer are shown in (c) at half-order ($Q_z=0.052\text{ \AA}^{-1}$) and (d) at first-order ($Q_z=0.099\text{ \AA}^{-1}$). The data represent an addition of the $(+ -)$ and $(- +)$ cross sections.

difficult to detect using x-ray-diffraction techniques.) In addition to forming Ag bridges spanning the magnetic layers, the annealing process could also act to reduce the population of pinholes in the Ag layer. Theoretical descriptions¹⁰ of such a system predict that the spin structure will change from ferromagnetic to antiferromagnetic as the defect density is decreased. This explanation of the magnetic changes is unlikely for our samples because it does not account for the emergence of micrometer-order, magnetic domains within the $\text{Ni}_{80}\text{Fe}_{20}$ layers.

In related discussions of these materials,^{4,7} it was instead suggested that the formation of in-plane domains increases the strength of the dipolar coupling between neighboring magnetic layers relative to competing ferromagnetic interactions. We have calculated⁵ the field required to overcome the dipolar force between two blocks separated by a distance s with antiparallel magnetization \mathbf{M} , as drawn in the inset of Fig. 3. Only the contributions of the magnetic flux from the ends of the block are significant for this configuration.

We consider blocks of equal height d , width W , and length L , though the expression can easily be generalized for other geometries. Integrating over the slab dimensions, we derive a general expression for the energy difference between the parallel and antiparallel configurations,

$$E_{\text{diff}} = M^2 \sum_{\alpha,\beta=1}^4 \sum_{\delta,\gamma=1}^2 \sigma_\delta \sigma_\gamma \left\{ |R_{\alpha,\beta,\delta,\gamma}| \left[\frac{1}{2} \epsilon_\beta X_\alpha^2 + \frac{1}{2} \epsilon_\alpha Z_\beta \dot{Z}_\beta + \frac{1}{3} \epsilon_\alpha \epsilon_\beta R_{\alpha,\beta,\delta,\gamma}^2 \right] + [X_\alpha^2 \dot{Z}_\beta + \frac{1}{2} \epsilon_\alpha \dot{Z}_\beta (X_\alpha^2 + Y_{\delta,\gamma}^2)] \ln(|R_{\alpha,\beta,\delta,\gamma}| + Z_\beta) + [X_\alpha Z_\beta \dot{Z}_\beta + \frac{1}{2} \epsilon_\beta X_\alpha (Z_\beta^2 + Y_{\delta,\gamma}^2)] \ln(|R_{\alpha,\beta,\delta,\gamma}| + X_\alpha) - X_\alpha \dot{Z}_\beta |Y_{\delta,\gamma}| \tan^{-1} \left(\frac{X_\alpha Z_\beta}{|Y_{\delta,\gamma}| |R_{\alpha,\beta,\delta,\gamma}|} \right) \right\}, \quad (1)$$

where $\epsilon = (-1, 1, 1, -1)$, $\sigma = (1, -1)$, $\mathbf{X} = (-W, 0, 0, W)$, $Y_{\delta,\gamma} = (\sigma_\delta - \sigma_\gamma)L/2$, $\mathbf{Z} = (s, d+s, d+s, 2d+s)$, $\dot{\mathbf{Z}} = (s, -d$

FIG. 3. Field $2H_c$ required to align blocks of spins calculated as a function of the in-plane domain width $W=L$. The dashed line represents the same calculation performed in the approximated case of $d, s \ll W, L$, as described in Ref. 6. The inset shows a schematic of the geometry used for these calculations.

$-s, -d-s, 2d+s)$, and $R_{\alpha,\beta,\delta,\gamma}^2 = X_\alpha^2 + Y_{\delta,\gamma}^2 + Z_\beta^2$. The field required to align the moments is $H_c = E_{\text{diff}}/2MWLd$.

$2H_c$ is plotted as a function of W in Fig. 3 for $d=20\text{ \AA}$, $d+s=60\text{ \AA}$, and $M=760\text{ emu/cm}^3$. (The alignment field is multiplied by two because each layer couples to two adjacent layers.) The field decreases gradually with increasing domain width W . For $W \approx 1.1\text{ }\mu\text{m}$, we calculate $2H_c=50\text{ Oe}$, which roughly matches the saturation field measured for the 335°C annealed multilayer. The magnitude of the magnetostatic interactions among the $1\text{--}5\text{ }\mu\text{m}$ magnetic domains is thus of the same order as that of the antiferromagnetic coupling.

By design, the complex structure of annealed $\text{Ni}_{80}\text{Fe}_{20}/\text{Ag}$ multilayers leads to low-field magnetic properties desirable for the fabrication of magnetic thin-film sensors. Using specular and off-specular PNR, we can directly probe the magnitude and direction of the magnetic moment as a function of depth and extract general features of the magnetic structure within the sample plane. We find that the in-plane magnetization of the $\text{Ni}_{80}\text{Fe}_{20}$ layers order in micrometer-sized domains after annealing and that antiferromagnetic correlations among these magnetic layers are responsible for the anomalous magnetoresistance in annealed multilayers.

Magnetization, magnetoresistance, and x-ray diffraction measurements of discontinuous $[\text{Ni}_{80}\text{Fe}_{20}/\text{Ag}]$ multilayers (abstract)

T. Lorenz, M. Moske, A. Käufler, H. Geisler, and K. Samwer
Universität Augsburg, Memminger Str. 6, D-86135 Augsburg, Germany

Thin films for magnetic sensor application require a high sensitivity at low magnetic fields, for example, realized by Permalloy films. Promising candidates for a further improvement are discontinuous multilayers, first reported by Hylton *et al.*¹ In our study, we report on $[2.5 \text{ nm Ni}_{80}\text{Fe}_{20}/y \text{ nm Ag}]$ multilayers with the spacer layer thickness y ranging from 1.2 nm to 6.0 nm. The multilayers were electron beam deposited in UHV at different temperatures. The substrates used are thermally oxidized silicon wafers. The magnetization is obtained using a vibrating sample magnetometer (VSM), the magnetoresistance is measured at room temperature with the Montgomery method. Low and high angle x-ray diffraction measurements are performed in a Siemens D-5000 diffractometer. The samples are annealed *ex situ* between room temperature and 340 °C. The magnetoresistance is maximal after annealing the samples at a specific temperature, which decreases with increasing Ag-spacer thickness y . Moreover, the GMR decreases if the multilayers are deposited at elevated temperatures (100–200 °C). We also report on the dependence of the GMR on the interface roughness ($\sigma \approx 0.5 \text{ nm rms}$) which we deduce from the small angle x-ray diffraction measurements. For a characterization of the reliability, we also investigated the dependence of the GMR on aging at 100 °C for several hours. © 1996 American Institute of Physics. [S0021-8979(96)59908-1]

Exchange coupling in sputtered giant magnetoresistance NiFe/Cu/CoFe/Cu multilayers

M. T. Kief, J. Bresowar, and Q. Leng

Department of Physics, MINT, Box 870209, University of Alabama, Tuscaloosa, Alabama 35487-0209

We will report on the exchange coupling, magnetoresistance (MR) and film structure in the system NiFe/Cu/CoFe/Cu as a function of multilayer number (bilayers=6 to 20) and Cu spacing (5 to 31 Å). The multilayers were prepared by sputter deposition and investigated by x-ray diffraction (XRD), atomic force microscopy (AFM), vibrating sample magnetometry (VSM), ferromagnetic resonance (FMR), and standard MR methods. The exchange coupling, H_{ex} , and MR are shown to vary with Cu spacing. The XRD data indicates the multilayer structure is evolving through at least the first 20 bilayers. AFM measurements suggest subtle variations in interface quality and a rms roughness near 0.4 nm. These variations in structure are manifested in the FMR and MR. Multilayers with Cu spacers >11 Å generally show the expected two FMR peaks. Some multilayers show three peaks indicating defects within the multilayer. These defects can be viewed as the elusive "pinholes" which act to ferromagnetically short the magnetic layers together. This demonstrates that FMR provides very valuable information about defects in nonideal multilayers which is critical to our understanding and applications of giant magnetoresistance (GMR) systems. © 1996 American Institute of Physics. [S0021-8979(96)79208-9]

MOTIVATION

Giant magnetoresistance (GMR) in multilayer systems requires that the magnetization in the magnetic layers alternate in different directions. Since the change in resistance varies as the $\cos(\theta)$, where θ is the relative angle between the magnetizations in alternate layers, the more closely the magnetizations orient antiparallel for zero applied field, the greater the magnitude of the GMR will be. The most common method to obtain this alternating variation in magnetization directions relies upon the oscillatory exchange coupling known to exist in such structures. It is often observed that changing the growth conditions can significantly alter the oscillatory coupling and thereby effect the GMR. It is commonly assumed that changes in multilayer microstructure such as surface roughness, interface mixing and thickness nonuniformity are responsible for the changes. However, the effect of these microstructures is not necessarily bad. For example, multilayers grown by sputtering often exhibit a decreased exchange coupling strength when compared to molecular beam epitaxy (MBE) prepared multilayers. For many applications (such as magnetic recording heads), a weak exchange coupling is very desirable. For this and many other reasons sputtering is often the method of choice.

Perhaps the most pervasive problem in all multilayers are defects which act to disrupt the desired antiparallel orientation. These defects, of various origins, are often called "pinholes" since they act as effective magnetic short circuits between alternate magnetic layers causing them to be pinned together due to strong ferromagnetic coupling. Although these "pinholes" are often blamed for poor results, it has been very difficult to verify the existence of them buried well within a multilayer and, in addition, to quantify their effects. In fact, the only direct observation that these authors are aware of is in simple magnetic sandwiches studied by Kerr microscopy.¹ There is a clear need to understand the role of microstructural nonidealities upon the exchange coupling in

genuine multilayers and without requiring special sample preparation.

In this article we will report a study of exchange coupling in a GMR multilayer system prepared by sputter deposition. The purpose of this investigation has been to better understand these phenomena in multilayers with less than ideal microstructures. We hope that this system will serve a prototype of many others.

EXPERIMENTAL APPROACH

In order to understand the effect of structure upon the exchange coupling and the GMR it was necessary to devise a method to quantify these properties as well as the structure of the multilayer film itself. A direct measurement of the exchange coupling strength in both the ferromagnetic and antiferromagnetic coupling states is provided by ferromagnetic resonance (FMR). This technique has been employed by a few groups to determine the exchange coupling strength in MBE prepared trilayers²⁻⁴ and sputter prepared trilayers.^{5,6} A principle requirement to permit the determination of the coupling strength is that the magnetic layers must be magnetically distinct in order to break the degeneracy and permit the observation of both the acoustic and optical modes which occur at different applied magnetic fields. It is the separation of these modes which is related to the interlayer exchange coupling strength. A detailed discussion of the FMR technique and analysis will be published elsewhere.⁷

For the above reasons, we decided to investigate the system NiFe/Cu/CoFe/Cu. The target compositions were Ni₈₀Fe₂₀, Cu, and Co₉₀Fe₁₀. Since the saturation magnetization of Co₉₀Fe₁₀ is roughly twice that of Ni₈₀Fe₂₀, this assures a nondegenerate system for FMR characterization. FMR measurements were conducted on a homemade system at a Q-band frequency of 34.5 GHz.

The multilayer films were sequentially prepared by computer control of our Vac-Tec sputter system. The system base

FIG. 1. Low-angle x-ray two-theta diffraction scans for 6, 14, and 20 BL with a Cu spacer layer thickness of 25 Å. Decreasing amplitude of the superlattice peaks indicates a loss of coherency with increasing BL number.

pressure is typically 2.0×10^{-7} mTorr. All films were deposited by dc (Cu) or dc-magnetron (NiFe, CoFe) sputtering at a pressure of 2.5×10^{-3} mTorr at ambient temperatures with deposition rates near 6 Å/s. All films were deposited upon Corning Glass #7059 glass substrates.

It is expected that the structure of the multilayers will depend upon the film thicknesses and the number of layers in the multilayer. In order to investigate the effects of the changing structure, we prepared sets of samples with varying Cu thickness (5 to 31 Å) and different layer number [6, 10, 14, and 20 magnetic/nonmagnetic bilayers (BL)]. The magnetic layer thicknesses were fixed at 15 Å, which was found to provide satisfactory results. (Other combinations were also investigated, but are not presented here.⁷)

The structure of the films were characterized with low-angle and high-angle x-ray diffraction (XRD) and atomic force microscopy (AFM). The GMR was measured using the standard linear 4-point probe method. Vibrating sample magnetometry (VSM) and FMR were used to measure the magnetic properties.

RESULTS AND DISCUSSION

Figure 1 shows low angle XRD scans for 6, 14, and 20 BL with a Cu spacer thickness of 25 Å. The decreasing amplitude of the short period superlattice peaks indicates that the layering of the multilayers actually degrades with increasing multilayer number. A similar trend appears for other Cu thicknesses as well. Qualitatively these data suggest a loss of vertical coherency of the superlattice with increasing BL. Using the first and second Bragg peaks we estimate the BL period to be 36.5 ± 1 Å, which is within 10% of the expected 40 Å period.

High angle XRD scans were also measured (not shown). All the multilayers are polycrystalline and show a (111) texture which sharpens with increasing BL number and increasing Cu thickness. The grain size is estimated by the Scherrer formula to be near 100 Å for the 14 BL multilayers. The position of the peak indicates the multilayer lattice spacing is between the bulk Cu and bulk Ni spacing.

AFM in air was used to investigate the surface topology and roughness of the multilayers. No significant trend was found with changing Cu thickness and BL number. However,

FIG. 2. Magnetoresistance for varying Cu spacer layer thicknesses and BL number. The two peaks near 13 and 25 Å indicate antiferromagnetic inter-layer exchange coupling.

for all samples measured a 1×1 μm scan had a typical roughness estimated to be 0.3 to 0.4 nm rms and 2 nm peak-to-peak. If we compare these values with the average film thickness (1 to 3 nm), it is conceivable that the interface roughness may have a significant influence upon the exchange coupling.

In summary, these GMR multilayers are polycrystalline with a small grain size and relatively rough interfaces, but probably not unlike many other sputter prepared multilayers. Further structural studies are currently underway.

The magnetoresistance as a function of Cu spacer thickness and BL number is shown in Fig. 2. Two peaks are observed near 13 and 24 Å of Cu in the 14 BL samples where the interlayer exchange coupling is expected to be antiferromagnetic. These thicknesses (13, 24 Å) and 5, 19, 25, and 31 Å are also shown for 6, 10, and 20 BL. In general, the MR at 6, 10, and 20 BL appears to follow the 14 BL curve but no simple trend with BL number can be confirmed. In particular note that the 14 BL data lies below both the 10 and 20 BL data at 13 Å of Cu. No known difference in preparation can account for this unexpected result other than the fact that the 14 BL samples were prepared first. The most likely cause is unknown impurities or background contamination which alter the microstructure, although none have been detected prior to this study. We will show below that the FMR results are consistent with this interpretation.

Figure 3 shows the FMR absorption signal for BLs having 25 Å Cu spacers. All these samples show two peaks except the 14 BL sample which shows three peaks. The low field peak (6500 Oe) and the high field peak (9000 Oe) may be thought of as the CoFe and NiFe uniform mode absorption signals, respectively. Strictly speaking, they correspond to the acoustic and optical modes of the system. The middle peak observed for the 14 BL sample is believed to be a third magnetic phase which we will discuss below. The shift in peak field position with BL number indicates a systematic decrease in the magnetic moment of the layers. This is consistent with the low-angle XRD data that indicates an increase in layer roughness with BL number.

FIG. 3. Ferromagnetic resonance absorption spectra for 6, 10, 14, and 20 BL with a Cu spacer of 25 Å. Peaks near 6500 and 9000 Oe essentially correspond to absorption from the CoFe and NiFe layers, respectively. The separation of the peaks is due to the intrinsic difference in M_{sat} for the layers and the interlayer exchange coupling. The central peak indicated by an arrow for the 14 BL sample suggests absorption from a magnetic defect or "pinhole" (see text for discussion).

The separation of the FMR peaks, ΔH , is due to the difference in the effective saturation magnetization, M_{sat} , and the effective interlayer exchange coupling, J . Other studies have shown that for systems with nearly identical M_{sat} , $\Delta H = 4J$.^{2,3} In our system we must also account for the large differences in M_{sat} which produces a large intrinsic peak separation, $\Delta H_{\text{intrinsic}}$. $\Delta H_{\text{intrinsic}}$ was determined to have a value of 2300 Oe from separate experiments using 120 Å Cu spacers. Therefore, we can approximately relate the measured peak separation $\Delta H = \Delta H_{\text{intrinsic}} + 4J$.

Using this relation we can determine the interlayer exchange coupling in the multilayers directly. Figure 4 shows a plot of the exchange coupling versus Cu spacer thickness for 14 BL. In addition, we also show the saturation field determined from the MR profile for antiferromagnetically coupled multilayers. The agreement is good, especially considering the weak fields involved.

We now return to discussion of the middle FMR peak shown in 14 BL data of Fig. 3. It should be emphasized that this peak appears to be more the exception than the rule. Most of the samples do not show this peak. When the exchange coupling is small, as at 25 Å of Cu, the peak field position at which the absorption occurs is largely determined by the M_{sat} of the material. Therefore, the middle peak must arise from a component whose effective M_{sat} is approximately half way between CoFe and NiFe. We conclude that the middle peak should be assigned to a component acting as a strong ferromagnetically coupled or essentially alloyed CoFe/NiFe phase. This most likely arises from a "pinhole" in the Cu spacer layer which causes neighboring NiFe and CoFe layers to "short" together, disrupt the desired antiferromagnetic multilayer alignment and reduce the GMR. Numerical calculations of FMR absorption peaks also support

FIG. 4. The exchange coupling field determined by FMR and the saturation field of the MR is plotted versus Cu spacer layer thickness for 14 BL. The line is a guide to the eye following the FMR data. An oscillatory coupling is indicated with antiferromagnetic peaks near 13 and 25 Å, which is consistent with measured MR (Fig. 2). Note the 50-fold decrease in exchange coupling strength from 13 to 25 Å.

this proposed interpretation.⁷ Furthermore, the occurrence of these "pinholes" is not inconsistent with the multilayer structure and interface roughness as discussed above.

CONCLUSIONS

The structure of sputtered GMR multilayers evolves with BL number and Cu thickness. The MR varies with the microstructure and appears sensitive to subtle structural changes which are very difficult to observe by most methods. FMR is a simple and direct method to determine coupling strength and is consistent with MR estimates. FMR permits the measurement of local defects such as pinholes which have a significant effect upon the exchange coupling and MR in these structures. More work is needed to determine the origin of the defects.

Spin polarized neutron reflectometry measurements were performed on $\text{Ni}_{80}\text{Co}_{20}/\text{Cu}$ multilayers with a Cu spacer thickness of 20 Å, corresponding to the second oscillation peak in the magnetoresistance of the NiCo/Cu multilayer system. Measurements in a 15 Oe field indicate a nearly perfect antiferromagnetic stacking of the magnetic moments in successive $\text{Ni}_{80}\text{Co}_{20}$ layers. The existence of a small magnetic anisotropy in these magnetically soft multilayers leads to the canting of the magnetic moments at an angle of $\sim 70^\circ$ with respect to the neutron spin polarization. This interlayer antiferromagnetic coupling can be suppressed by an applied field of ~ 200 Oe.

INTRODUCTION

Giant magnetic resistance (GMR) in magnetic multilayers is strongly correlated to magnetic ordering within the multilayers as the latter determines the nature of the spin dependent electron scattering. The magnetic order in the magnetic multilayer is maintained via RKKY-type exchange coupling¹ between adjacent magnetic layers across the non-magnetic spacer thickness. The oscillatory behavior of GMR with increasing nonmagnetic spacer thickness results from an associated change in the exchange coupling from ferromagnetic (FM) to antiferromagnetic (AF).² $\text{Ni}_{80}\text{Co}_{20}/\text{Cu}$ multilayers show a low-field GMR ($\sim 1\%/\text{Oe}$) (Ref. 3) at a regime where the magnetic exchange coupling between adjacent magnetic layers is assumed to be relatively weak. In this case, the magnetic anisotropy, which may arise from either substrate clamping or interface strains, could play an important role in determining the magnetic structure. The magnetic moments in neighboring magnetic layers could be oriented at 90° to each other, or even display random relative orientations. Understanding the low-field GMR in the NiCo/Cu system requires a detailed knowledge about its magnetic structure. Spin polarized neutron reflectometry has proved to be a powerful tool for this purpose.⁴ It measures not only the nuclear and the magnetic scattering length profiles along the film growth direction but also provides information about the orientation profile of the average magnetization within the individual layers by distinguishing between two scattering processes. The nonspin-flip (NSF) scattering process probes the depth profile of the nuclear structure and the component of magnetic moment along the neutron spin polarization, while the spin-flip (SF) scattering process is solely attributed to the component of magnetic moment in the scattering plane.

EXPERIMENTAL TECHNIQUES

NiCo/Cu multilayers of structure $\text{Si}/(\text{Ni}_{80}\text{Co}_{20})_{50} \text{ Å} [\text{Cu}_{20} \text{ Å}/(\text{Ni}_{80}\text{Co}_{20})_{15} \text{ Å}]_n$ with bilayer repeat $n=12, 60$ were prepared by dc magnetron sputtering at McGill Univer-

sity. The deposition of a 50 Å $\text{Ni}_{80}\text{Co}_{20}$ buffer layer was expected to improve the structural perfection and to reduce the in-plane magnetic anisotropy.

Spin polarized neutron reflectometry measurements were carried out on the C5 triple-axis spectrometer at AECL, Chalk River Laboratories. The (111) Bragg reflection of a Cu_2MnAl Heusler single crystal selected a narrow band ($\Delta\lambda = 0.03$ Å) of incident neutrons with a wavelength of 2.3705 Å and down-spin polarization **P**. A PG filter was placed at the incident side of the sample to eliminate the higher order contamination. The monochromated neutron beam was highly collimated, giving rise to an angular divergence of full width at half-maximum $\sim 0.02^\circ$ at the sample. A second identical Heusler crystal was used to analyze the energy and polarization of scattered neutrons. The beam path was covered with permanent magnets, serving as the guide field, **H**, to prevent the neutron spin from depolarizing. The guide field at the sample position was 15 Oe. When used as an applied field, the magnitude of the guide field at the sample position could be increased to a level as high as 250 Oe. Two Mezei-type⁵ neutron spin flippers were installed in front of and after the sample in order to separate the NSF and SF scattering processes. The multilayer sample was first saturated under a magnetic field of 250 Oe before measurements were taken. The scattering intensities were measured in the usual $\theta-2\theta$ mode with the multilayer surface normal bisecting the incident and scattered wavevectors. Diffuse scattering underneath the specular ridge was measured by $(\theta - \delta\theta)-2\theta$ scans with a small offset in θ .

RESULTS AND DISCUSSION

The specular reflectivities for NSF (R^{++}, R^{--}) and SF (R^{+-}, R^{-+}) channels were extracted from the measured scattering intensities after the corrections from nonspecular contributions, finite sample size, polarization and spin-flipping efficiencies.⁶ Details will be described in a later publication. The reflectivities at 15 Oe field are shown in Fig. 1, where the two SF reflectivities, which are identical, have been added together to improve the statistics. While the data

FIG. 1. Specular reflectivity for NSF (R^{++}, R^{--}) and SF (R^{+-}, R^{-+}) scattering processes at 15 Oe field for two $[(\text{Ni}_{80}\text{Co}_{20})_{15}\text{Å}/\text{Cu}_{20}\text{Å}]_n$ multilayers: (a) $n=60$, (b) $n=12$. The two SF reflectivities have been added and translated downwards by three orders of magnitude. The inset illustrates an antiferromagnetic stacking of magnetic moments (antiparallel arrows) in adjacent NiCo/Cu layers, which orient at an angle, γ , to y -axis, and the scattering geometry with the wavevector transfer, Q , lying within the xz plane and parallel to the z -axis.

for the 12 repeat sample clearly shows an oscillatory nature to the scattering due to interference between the scattering from the two interfaces of the multilayer of finite thickness, the data for the 60 repeat sample exhibits pronounced scattering peaks, characterizing the multilayer superlattice structure. The following discussion will therefore be focussed on the 60 repeat sample.

The NSF data, R^{++} and R^{--} , at 15 Oe field show total external reflection at $Q_c=0.017 \text{ Å}^{-1}$ and a Bragg reflection at $Q_B=0.17 \text{ Å}^{-1}$, which corresponds to the bilayer periodicity of the multilayer, $\Lambda=d_{\text{NiCo}}+d_{\text{Cu}}$, 37 Å which is 2 Å larger than the nominal value. The total external reflection occurs at the same wave vector and the Bragg reflection shows the same intensity for the two NSF reflectivities. This indicates the absence of a ferromagnetic interlayer alignment for the 15 Oe applied field. Significant differences between the two NSF reflectivities, however, can be seen in the wave vector region, $Q \sim 0.06\text{--}0.08 \text{ Å}^{-1}$, which may be ascribed to either the presence of an $\sim 40 \text{ Å}$ ferromagnetically ordered $\text{Ni}_{80}\text{Co}_{20}\text{O}_x$ overlayer or most probably a few ferromagnetically coupled $\text{Ni}_{80}\text{Co}_{20}$ layers near the film surface. Further quantitative analysis on this phenomenon is in progress.

The SF data for the 15 Oe applied field do not show total external reflection. The reflectivity peaks at $Q=0.087 \text{ Å}^{-1}$ ($\sim Q_B/2$), indicating the existence of a periodic structure with twice the periodicity of the bilayer thickness in the multilayer. The fact that SF data are only sensitive to the component of magnetic moment, μ_x , within the scattering plane indicates an AF stacking of this component along the growth direction. An estimate from the preliminary model

FIG. 2. Specular reflectivity for NSF (R^{++}, R^{--}) and SF (R^{+-}, R^{-+}) scattering processes at 230 Oe field for the 60 repeat sample. The inset shows that the magnetic moments (parallel arrows) in adjacent NiCo/Cu layers order ferromagnetically.

calculation gives a value of $\mu_x=(0.71 \pm 0.10)\mu_B$ per atom. Furthermore, the absence of Bragg scattering at Q_B is also indicative of zero net ferromagnetic order within the scattering plane at the 15 Oe field.

In addition to these major features, a very weak peak can also be seen at $Q_B/2$ on the NSF data. The periodicity and the weakness of this scattering implies that an AF alignment of a small component of magnetic moment (μ_y) along the neutron polarization direction (estimated at $0.25\mu_B$ per atom) exists. This can be attributed to the existence of a very weak magnetic anisotropy in the multilayers, which favors the alignment of the magnetic moments in adjacent $\text{Ni}_{80}\text{Co}_{20}$ layers at an angle of $\gamma \sim 70^\circ$ to the y -axis, as demonstrated by the inset in Fig. 1.

Upon increasing the guide field at the sample to 230 Oe, the most pronounced feature observed on the reflectivities is the disappearance of the half order peaks on all four scattering cross sections, as shown in Fig. 2. No scattering contribution from the SF process is seen within the background level. The critical wave vector for the total external reflection splits for the two NSF reflectivities as does the Bragg scattering intensity at Q_B . This indicates that the AF order has been destroyed at a field of 230 Oe. FM order forms as the applied field forces the magnetic domains to align along the field direction. Constructive and destructive interference between the nuclear and the magnetic Bragg scattering from a FM ordered interlayer structure gives rise to the asymmetry for the NSF data. The difference of the scattering intensity for the NSF data in the wavevector region from 0.06 to 0.08 Å^{-1} , as noticed above from the 15 Oe field data, remains unchanged at the 230 Oe field, confirming its ferromagnetic origin.

CONCLUSIONS

The low-field $\text{Ni}_{80}\text{Co}_{20}/\text{Cu}$ multilayers at the chosen Cu spacer thickness of 20 Å possess a nearly perfect antiferromagnetic order along the film growth direction at a 15 Oe applied magnetic field. The total magnetic moment of the $\text{Ni}_{80}\text{Co}_{20}$ layer has been estimated to be $0.75\mu_B$ per atom, close to its bulk value of $0.82\mu_B$ per atom. The existence of a small magnetic anisotropy causes the magnetic moment to align along a direction of $\sim 70^\circ$ with respect to the neutron spin polarization.

The transition of the AF order to FM order is seen to be complete by a field of 230 Oe. It is expected that the ongoing neutron and x-ray scattering analysis will give more detailed information about the spatial distribution and coherency of the magnetic structure in $\text{Ni}_{80}\text{Co}_{20}/\text{Cu}$ magnetic multilayers and shed more light on the complexity of the NSF data in the wavevector region from 0.06 to 0.08 \AA^{-1} .

Fe/Si multilayers with antiferromagnetic interlayer coupling have been grown via ion-beam sputtering on both glass and single-crystal substrates. High-angle x-ray diffraction measurements show that both sets of films have narrow Fe peaks, implying a large crystallite size and crystalline iron silicide spacer layers. Low-angle x-ray diffraction measurements show that films grown on glass have rougher interfaces than those grown on single-crystal substrates. The multilayers grown on glass have a larger remanent magnetization than the multilayers grown on single-crystal substrates. The observation of magnetocrystalline anisotropy in hysteresis loops and (*hkl*) peaks in x-ray diffraction demonstrates that the films grown on MgO and Ge are epitaxial. The smaller remanent magnetization in Fe/Si multilayers with better layering suggests that the remanence is not an intrinsic property. © 1996 American Institute of Physics. [S0021-8979(96)51208-4]

I. INTRODUCTION

The well-established picture of antiferromagnetic coupling in metal/metal multilayers would have to be extensively modified for coupling across insulating or semiconducting spacer layers, where the spacer does not possess a Fermi surface.^{1,2} In particular the temperature dependence of the exchange coupling might be significantly different in ferromagnet/semiconductor multilayers where the exchange is mediated by thermally activated carriers.¹

Unusual temperature-dependent magnetic properties have been reported for Fe/Si multilayers. For example, a large increase in the remanent magnetization has been observed at low temperature.³ If the interlayer antiferromagnetic (AF) coupling increases with decreasing temperature, as in multilayers with metal spacers, one might expect the remanence instead to *decrease* at low temperature. Proper interpretation of the remanent magnetization in Fe/Si multilayers may therefore be important to understanding the origin of the interlayer coupling in this system. One way to explore the origin of the remanence is to compare films of different crystalline quality.

II. EXPERIMENTAL METHODS

The films used in this study were grown using ion-beam sputtering (IBS) in a chamber with a base pressure of 2×10^{-8} Torr. The deposition system is described in more detail elsewhere.⁴ All samples used in this study were grown at a substrate temperature of 200 °C. All comparisons between films grown on glass and single-crystal substrates will be made on samples which were deposited *simultaneously* so as to eliminate any reproducibility issues.

The substrates used in this study were glass coverslips, MgO (001), Ge(001), and Al₂O₃(11 $\bar{2}$ 0). The MgO and Al₂O₃ substrates were cleaned according to a recipe reported by Farrow and co-workers.⁵ The glass and Ge substrates were rinsed in solvents. All films are capped with a 200 Å Ge oxidation barrier. The magnetic and structural properties of the films are stable for at least one year.

III. STRUCTURAL CHARACTERIZATION

Figure 1 shows high-angle x-ray diffraction spectra for a purely (001)-oriented (Fe40 Å/Si14 Å)×60 multilayer grown on MgO(001) and a purely (011)-oriented multilayer grown simultaneously on glass. While multiple superlattice satellites are observed around the Fe(002) peak for the film grown on MgO, the film on glass has only one peak corresponding to (011)-textured growth. A single superlattice satellite is typically observed in multilayers on glass on the low-angle side in keeping with previous observations.⁶ An estimate of the crystallite sizes in these films can be derived using the Scherrer formula. This analysis gives a coherence length of 165 Å for the film on glass and 188 Å for the film on MgO.

One possible explanation for the lack of satellite peaks in the film grown on glass might be different interference conditions in the (011) orientation. However, the diffraction spectrum of a (Fe40 Å/Si14 Å)×46 (011)-oriented multilayer grown on Al₂O₃ (not shown) has even stronger satellites than the (001)-oriented multilayers grown on MgO. The evidence therefore suggests that the presence of high-angle satellites in the film on MgO must be due to better layering, not better crystallinity or orientation. The small-angle x-ray scattering data shown in Fig. 2 confirm this hypothesis. The multilayer on MgO has four low-angle peaks, indicating a moderate degree of composition modulation. The multilayer on glass shows only two relatively broad peaks, indicating larger interfacial roughness and less order in the layering. The low-angle x-ray spectra are consistent with rocking curves which are only about 1° wide for films grown on MgO and Al₂O₃ but are typically 10° to 15° wide for films on glass. The bilayer periods determined from the low-angle peak positions are (41.0 ± 0.1) Å for the MgO film and (40.9 ± 0.2) Å for the glass film, the same within experimental error.

ϕ scans of the MgO and Fe [110] peaks for the film on the MgO substrate (not shown) demonstrate that it is oriented in-plane. While θ -2 θ scans for (011)-oriented multilayers grown on Al₂O₃ substrates (not shown) also show multiple

FIG. 1. High-angle x-ray diffraction spectra from two $(\text{Fe}40 \text{ \AA}/\text{Si}14 \text{ \AA}) \times 60$ multilayers grown on different substrates. High-angle x-ray peaks give information about lattice constants and stacking within the layers. The multilayer grown on $\text{MgO}(001)$ has an $\text{Fe}(002)$ peak with four satellites. The multilayer simultaneously grown on glass has only an $\text{Fe}(011)$ peak.

high-angle superlattice satellites, the ϕ scans for this film indicate only weak orientation in-plane.

The shape of the high-angle peaks and their superlattice satellites are described by a well-known theory.⁷ Application of this theory to the Fe/Si multilayers is difficult because the iron silicide lattice constant, the thickness of the remaining pure Fe, and the thickness of the iron silicide spacer can be estimated only roughly. A precise determination of the silicide lattice constant should make a quantitative analysis of these satellite features possible.

IV. MAGNETIC CHARACTERIZATION

Figure 3(a) shows magnetization curves for 60-repeat $(\text{Fe}40 \text{ \AA}/\text{Si}14 \text{ \AA})$ multilayers grown simultaneously on glass

FIG. 2. Low-angle x-ray diffraction spectra for the same two $(\text{Fe}40 \text{ \AA}/\text{Si}14 \text{ \AA}) \times 60$ multilayers. Low-angle x-ray peaks give information about the bilayer period and layering of the multilayer. The multilayer grown on MgO has four relatively narrow peaks. The multilayer grown on glass has only two broad peaks, indicating a greater degree of interface roughness.

FIG. 3. Magnetization curves for Fe/Si multilayers grown on various substrates. The magnetization data is normalized to the highest measured value in order to facilitate comparison of the shape of the two data sets. (a) Hysteresis loops for the $(\text{Fe}40 \text{ \AA}/\text{Si}14 \text{ \AA}) \times 60$ multilayers simultaneously grown on $\text{MgO}(001)$ and glass. The remanence is lower for the film grown on MgO . (b) Hysteresis loops for $(\text{Fe}100 \text{ \AA}/\text{Si}14 \text{ \AA}) \times 2$ multilayers (trilayers) grown on $\text{Al}_2\text{O}_3(11\bar{2}0)$, $\text{Ge}(001)$, and $\text{MgO}(001)$. All data are taken with the applied magnetic field along the $\text{Fe}(100)$ easy direction.

and $\text{MgO}(001)$. The saturation fields H_s appear to be similar for the two films. On the other hand, the remanent magnetization is 58% for the film on glass and 7% for the film grown on MgO . A remanence as low as 1% has been observed for other multilayers grown on MgO substrates. Superconducting quantum interference device (SQUID) magnetometer data taken up to higher fields gives a saturation field of 9.75 kOe for the multilayer on MgO at room temperature. Assuming for a moment that the interlayer coupling is purely bilinear in nature, a well-known formula relates the saturation field to the AF coupling strength: $A_{12} = H_s M_s t_{\text{Fe}} / 4$ where M_s is the saturation magnetization and t_{Fe} is the thickness of an individual Fe layer.⁸ Use of this equation with $H_s = 9.75$ kOe and the measured magnetization $M_s = 1271 \text{ emu/cm}^3$ gives $A_{12} = 1.2 \text{ erg/cm}^2$. This AF coupling value is comparable in size to the coupling measured in metal/metal multilayers.⁹

Figure 3(b) shows magnetization curves for Fe100 Å/Si14 Å/Fe100 Å trilayer films grown on Al₂O₃ (11 $\bar{2}$ 0), Ge(001), and MgO(001) substrates. All three of the magnetization curves in Fig. 3(b) were taken with the field applied along an Fe(100) easy direction. Significant in-plane anisotropy of the magnetization curves occurs for the films on the Ge and MgO substrates, similar to what has been observed for Fe/Cr/Fe trilayers.⁸ The observation of magnetocrystalline anisotropy in the film on MgO but not in the film grown on Al₂O₃ is consistent with expectations from the ϕ scans, which show that the in-plane orientation of the film on MgO is much stronger.

Figure 3(b) once again demonstrates that the degree of remanence in Fe/Si multilayers is strongly related to the quality of layering. While the remanent magnetization of the epitaxial trilayers on Ge and MgO is only about 5% of the saturated value, the remanence of the polycrystalline trilayer on Al₂O₃ is close to 50%. The remanent magnetization of the trilayers on Ge and MgO is about 5% in the in-plane hard direction ($H \parallel$ Fe(110)) as well.

A SQUID magnetometer has been used to measure the magnetization curves of the IBS-grown Fe/Si multilayers at lower temperatures.¹⁰ The temperature dependence of the remanent magnetization of these films is similar to that reported by other authors.³

V. DISCUSSION

At the moment it is not possible to tell why the in-plane ordering of the films grown on Al₂O₃(11 $\bar{2}$ 0) is inferior to that grown on the (001) MgO and Ge substrates. The difficulty with the Al₂O₃ growth may have to do with the 6° miscut of the substrates, or it may be due to an intrinsic difficulty with (011) growth of the Fe/Si multilayers. Previous work has shown that AF coupling in Fe/Si multilayers is dependent upon formation of a metastable iron silicide spacer layer phase.⁴ The possibility exists that the spacer silicide does not grow well on Fe in the (011) orientation. This question can be answered only by further growth studies on better (011) substrates and careful structural characterizations.

A related question is whether the larger remanent magnet moment in the (011)-textured films might be due to a fundamental difference in magnetic properties from the (001)-textured films. Because a 46-repeat Fe/Si multilayer grown on Al₂O₃ has a remanence of only about 10%, this is unlikely. Undoubtedly the trilayer on Al₂O₃ has a higher remanence than the multilayer because the thinner film is more greatly impacted by the poor substrate surface quality. The staircase morphology caused by the 6° miscut of this Al₂O₃ substrate may lead to wavy interfaces between the Fe and iron silicide films or to pinholes through the silicide layers. Wavy interfaces can cause increased magnetostatic

coupling or even biquadratic coupling,¹¹ both of which would tend to increase the remanence. The large remanence of the multilayers grown on glass substrates is likely also due to pinholes or magnetostatic coupling.

Pinhole-induced coupling may explain the unusual temperature dependence of the remanence. (Magnetostatic coupling is expected to be approximately temperature-independent.) Fe atoms in bridges through the silicide spacer layers are expected to have a reduced Curie temperature. A larger remanence at low temperature therefore makes sense if the remanence is derived from pinhole coupling and is not an intrinsic effect. Low Curie temperature material may also be present in the iron silicide spacer layer or in at the iron/iron silicide interfaces.

By growing on a number of substrate materials and by using different deposition conditions, Fe/Si multilayers have been prepared with a varying degree of ordering. A large amount of accumulated evidence demonstrates that high remanence of the magnetization curves in Fe/Si multilayers is associated with interface roughness. The remanence is therefore not likely to be related to unusual exchange coupling but instead to originate from defects, perhaps pinholes through the silicide spacer layer. Since the remanent magnetization is caused by extrinsic effects, future studies should concentrate instead on measurements of the saturation field of the magnetization curves in order to learn more about the interlayer coupling.

The magnetic coupling of the Fe layers in Fe/Si multilayers strongly depends on the morphology of the iron-silicide interlayer that forms during deposition. Antiferromagnetic interlayer coupling is only observed in Fe/Si multilayers with crystalline interlayers in the CsCl structure.¹ Recently, it has been shown that single layers of Fe-Si in the CsCl structure can be grown epitaxially on Si over a range of stoichiometries.² FeSi films are reported to be Kondo insulators below 50 K. We find evidence of a magnetic phase transition in antiferromagnetically coupled Fe/Si multilayers. M_s measured in a constant applied field of 50 kOe shows $T^{3/2}$ behavior down to 10 K. However, $M(T)$ at a lower constant field peaks around 50 K and decreases at lower temperature, indicating enhanced antiferromagnetic coupling or a phase transition. The remanent magnetization increases monotonically with decreasing temperature and has been explained by invoking thermally activated coupling. However, the saturation field also increases with decreasing temperature, indicating a stronger antiferromagnetic interaction. We explore the suggestion³ that the interlayer coupling is biquadratic in nature. Polarized neutron reflectometry has also been used to get a clearer picture of the complicated magnetic behavior of this multilayer system. © 1996 American Institute of Physics. Antiferromagnetic coupling in magnetic multilayers with a narrow gap semiconductor spacer

Zhu-Pei Shi and Barry M. Klein

Department of Physics, University of California, Davis, California 95616

Antiferromagnetic (AF) coupling has been observed in sputtered Fe/Si multilayers at room temperature, with thin spacers (<20 Å) which were claimed to be FeSi. To study the magnetic coupling in this system we extend the RKKY interaction approach to a temperature-dependent narrow gap semiconductor. The strong AF coupling at room temperature and weakly ferromagnetic (F) coupling at low temperatures observed in Fe/Si can be explained from this model. © 1996 American Institute of Physics. [S0021-8979(96)51308-3]

The first evidence for AF coupling of magnetic multilayers via a transition-metal spacer was made in crystalline bcc (001) Fe/9 Å Cr/Fe sandwiches¹ using Brillouin light scattering and magneto-optical Kerr hysteresis loops. Interest in the Fe/Cr systems was heightened by the subsequent observation that the resistance of AF coupled (001) Fe/Cr multilayers² decreases enormously with the application of a magnetic field, a phenomenon called giant magnetoresistance. The oscillatory behavior of the magnetic coupling³ has sparked tremendous interest in *metallic* multilayered structures. The oscillation periods of interlayer magnetic coupling have been successfully explained by applying RKKY-like interactions to the layered geometry and using the Fermi surface characteristics of the metal spacers.⁴

AF interlayer coupling was discovered in evaporated Fe/Si/Fe trilayers⁵ and sputtered Fe/Si multilayers,⁶ in which spacers are apparently *nonmetallic*. AF coupling in the multilayers was observed with crystalline spacer layer,⁶ attributed to iron silicide (FeSi) formed in the interfaces, while in the trilayers the spacer was claimed to be amorphous semiconductor Si (*a*-Si).⁵ The different spacers may originate from the differences in the preparation methods and the substrate temperatures used, because Fe and Si easily form an alloy. Inomata *et al.*⁷ claimed that their Si spacer layers are an FeSi compound when the Si layer is less than 15 Å and is a combination of this silicide and amorphous Si when the Si spacer thickness is greater than 15 Å. Recently, Foiles *et al.*⁸ used transmission electron diffraction to obtain direct evidence for iron silicides in sputtered Fe/Si multilayers. In this article we theoretically investigate the mechanism of AF coupling in sputtered Fe/Si multilayers where the thin spacer is treated as ϵ -FeSi (rock-salt-like structure).

Band structure calculations predict a small semiconductor gap (67 meV in Ref. 9, 87 meV in Ref. 10, and 110 meV in Ref. 11) for ϵ -FeSi. Chainani *et al.*¹² reported high-resolution temperature-dependent photoemission spectra of ϵ -FeSi which show an extremely small gap of less than 5 meV. Here, we extend RKKY interaction theory between two magnetic moments in a semiconductor¹³ to two magnetic sheets in a crystalline semiconductor with a narrow gap.

At finite temperatures, one may expect a considerable number of thermal electrons in the conduction band and holes in the valence band for a narrow gap semiconductor. Assuming the interaction between conduction electrons or holes and local spins has a form $H_{\text{int}} = A \sum_i \sigma_i \cdot \mathbf{S}_i \delta(\mathbf{r} - \mathbf{r}_i)$, one

obtains an RKKY coupling, in reciprocal space, as

$$j_{\text{RKKY}}(\mathbf{q}) = A^2 \sum_{n_1, n_2, \mathbf{k}} \frac{f_{n_1 \mathbf{k}} - f_{n_2 \mathbf{k}'}}{\epsilon_{n_2 \mathbf{k}'} - \epsilon_{n_1 \mathbf{k}}}, \quad (1)$$

where $\mathbf{k}' = \mathbf{k} + \mathbf{q} + \mathbf{G}$ and \mathbf{G} is a vector of the reciprocal lattice. $f_{n\mathbf{k}}$ is the Fermi distribution function for Bloch states $n\mathbf{k}$. For simplicity, we assume the free-electron gas approximation for the thermally activated electrons in the conduction bands and the holes in the valence bands. A simple conduction electron band for the spacer may be taken as

$$\epsilon_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m^*} + \frac{E_g}{2}, \quad (2)$$

where m^* is an effective mass, and E_g is an energy gap. According to Yafet's argument,¹⁴ the RKKY coupling between two sheets of spins can be obtained directly by Fourier transforming Eq. (1), and is given as

$$J_{\text{RKKY}}(z) = \frac{a}{2\pi} \int_0^\infty dq_z j_{\text{RKKY}}(q_z) \cos(q_z z), \quad (3)$$

where $a = 4.493$ Å is the lattice constant of ϵ -FeSi.

Given an energy gap and effective mass, the RKKY coupling can be estimated at finite temperatures from Eqs. (1)–(3). AF coupling can be obtained at finite temperatures in a narrow region of spacer thickness when the energy gap becomes very small. For example, we set $E_g = 50$ K (4.3 meV, a possible extremely small gap¹²) and temperature $T = 300$ K, and $J_{\text{RKKY}}(z)$ for $m^* = m_e$, $2m_e$, and $4m_e$ are then obtained and plotted in Fig. 1, as a solid line, dashed line, and dotted line, respectively. We see that AF coupling occurs when the spacer thickness is $20 \text{ Å} < z < 35 \text{ Å}$, $14 \text{ Å} < z < 22 \text{ Å}$, and $10 \text{ Å} < z < 17 \text{ Å}$ for $m^* = m_e$, $2m_e$, and $4m_e$, respectively. The result for the case $m^* = 4m_e$ agrees well with experiments^{6,7} where AF coupling at room temperature appears when the spacer thickness is between 11 and 17 Å.

Next we study the effect of energy gap at room temperature. Fixing the thickness of the spacer at $z = 13$ Å, RKKY couplings for $m^* = m_e$, $2m_e$, and $4m_e$ are then obtained and plotted in Fig. 2, as a dotted line, dashed line, and solid line, respectively. We see that the AF coupling can be obtained for an energy gap up to 900 K for $m^* = 4m_e$.

With decreasing temperature, experiments^{6,7} indicated that the AF coupling at room temperature will disappear and the coupling in sputtered Fe/Si multilayers becomes *weakly*

FIG. 1. Thickness dependence of RKKY coupling $J_{\text{RKKY}}(z)$ at temperature $T=300$ K and energy gap $E_g=50$ K. Solid line, dashed line, and dotted line are for effective mass $m^*=m_e$, $2m_e$, and $4m_e$, respectively. AF coupling occurs.

ferromagnetic (F) at low temperatures, e.g., $T=50$ K. We fix the values of the energy gap $E_g=50$ K and effective mass $m^*=4m_e$. The RKKY coupling $J_{\text{RKKY}}(z)$ at low temperature $T=50$ K is computed and plotted in Fig. 3, as a dotted line. We replot the result for $T=300$ K in Fig. 3, as a solid line, for comparison. For spacer thickness $11 \text{ Å} < z < 17 \text{ Å}$, the AF coupling at room temperature becomes *strong* F coupling at the low temperature $T=50$ K. This feature of the temperature dependence of the interlayer coupling is in contrast to the experimental observations^{6,7} mentioned above. We conclude that the results of RKKY coupling based on a *rigid* small energy gap existing in the spacer cannot fully explain the interlayer magnetic coupling in sputtered Fe/Si multilayers.

It has been suggested that the transition-metal compound FeSi may belong to the class of strongly correlated materials known as Kondo insulators (hybridization semiconductor).¹⁵ One of the salient features of a Kondo insulator is the temperature-dependent hybridization gap $E_g(T)$.¹⁵ The en-

FIG. 2. RKKY coupling $J_{\text{RKKY}}(E_g)$ as a function of energy gap. Dotted line, dashed line, and solid line are for effective mass $m^*=m_e$, $2m_e$, and $4m_e$, respectively.

FIG. 3. RKKY coupling $J_{\text{RKKY}}(z)$ as a function of spacer thickness. A solid line with AF coupling is for $T=300$ K and $E_g=50$ K. Dotted line and dashed line are for $E_g=50$ K and $E_g=400$ K at $T=50$ K, respectively.

ergy gap at $T=0$ decreases with increasing temperature, and it becomes very small at relatively high temperatures.¹⁶

Fixing the values of $T=50$ K and $m^*=4m_e$, RKKY coupling $J_{\text{RKKY}}(z)$ for $E_g=400$ K is calculated and plotted in Fig. 3, as a dashed line. This coupling is weak F because of the relatively large energy gap as we expect. For spacer thickness $11 \text{ Å} < z < 17 \text{ Å}$, the desired (observed) coupling behavior in sputtered Fe/Si multilayers, in which the AF coupling at room temperature (solid line in Fig. 3) becomes very *weak* F at low temperatures, e.g., $T=50$ K (dashed line in Fig. 3), is obtained.

The model calculations we described above explain the experimental results for a crystalline spacer with a very narrow gap. But this model does not provide an AF coupling at room temperature or low temperatures for spacer materials with a much larger gap, e.g., *a*-Si ($E_g \approx 0.4$ eV). The quantum interference approach with complex Fermi surface¹⁷ produces an AF coupling at finite temperatures for spacers with a large energy gap. But this theoretical framework cannot explain the temperature-dependent AF coupling observed in experiments.^{7,18} The mechanism of AF coupling through an *a*-Si spacer is still an open question, perhaps driven by defect states.

In conclusion, we modeled the spacer in sputtered Fe/Si multilayers as a *temperature-dependent narrow gap* semiconductor (ϵ -FeSi). We showed that the temperature-induced AF coupling at room temperature becoming weak F coupling at low temperatures for small thicknesses of the spacer in sputtered Fe/Si multilayers can be interpreted in terms of an RKKY-like interaction.

Magnetic properties of $(1\bar{1}02)$ Dy/Y superlattices

K. Theis-Bröhl,^{a)} K. A. Ritley, and C. P. Flynn

Department of Physics, University of Illinois, 1110 West Green Street, Urbana, Illinois 61801-3080

K. Hamacher, H. Kaiser and J. J. Rhyne

Research Reactor Center, University of Missouri-Columbia, Columbia, Missouri 65211

Epitaxial $(1\bar{1}02)$ Dy/Y rare earth superlattices and a thick $(1\bar{1}02)$ Dy film, grown on sapphire with Y/Ta buffer layers, have been prepared by molecular beam epitaxy. Neutron diffraction and SQUID magnetization measurements on a single 200 nm thick $(1\bar{1}02)$ Dy layer showed nearly bulk behavior. However, for the $(1\bar{1}02)$ Dy/Y superlattices we found different magnetic behavior depending on the relative Dy to Y-layer thickness. The superlattices exhibit both ferromagnetic and helical phases, but with the Néel and Curie temperatures significantly different from bulk Dy. These results differ from previous findings in Dy/Y superlattices grown along $[0001]$. © 1996 American Institute of Physics. [S0021-8979(96)79108-2]

Extensive studies of the magnetism of (0002) Dy/Y superlattices (SLs) show a long-range indirect exchange coupling of the heavy rare-earth Dy through the Y spacer material.¹ Deviating from the bulk behavior of Dy (which shows a ferromagnetic phase with a Curie temperature at 85 K and a helimagnetic phase with a Néel temperature at 185 K)² the ferromagnetic phase in the (0002) Dy/Y superlattices is completely suppressed by epitaxial strain. Neutron diffraction scans of the (0002) Dy/Y superlattices showed only helical antiferromagnetism down to 5 K.¹ Studies of Dy/Y superlattices grown in *a*- and *b*-orientation (*c*-axis in the film plane) show a similar phase diagram to the *c*-axis grown superlattices;^{3,4} however, only single-layer ordering was observed and the long-range 3D-magnetic ordering was destroyed. The observed weak coupling was attributed to the directional dependence of the conduction electron response.

This paper reports results on a series of $(1\bar{1}02)$ Dy/Y superlattices and films for which the angle between the growth orientation and the *c*-axis is close to 45°. Coupling between successive planes should therefore be affected by this angle. Due to the off *c*-axis growth direction the magnetic domain size within the (0002) plane has to be limited by the Dy-layer thickness.

The samples were grown at the University of Illinois. A $(1\bar{1}00)$ sapphire substrate with an 1.5° miscut along the $[11\bar{2}0]$ orientation was used to avoid the growth of a second $(1\bar{1}02)$ Dy/Y structural domain.⁵ The sapphire was annealed for 1 h at 1200 °C before depositing a 75 nm thick Ta(211) buffer (growth temperature 960 °C). A 100 nm thick $(1\bar{1}02)$ Y buffer layer was grown on the Ta at a growth temperature of 500 °C, and was found to grow tilted at an angle of about 5° to the Al₂O₃ and to form facets.⁵ On the Y buffer we have grown the Dy/Y superlattice at a growth temperature that avoids interdiffusion. Finally, we protected our superlattices with a 15 nm thick Y toplayer.

To confirm the quality of the samples and to find the superlattice periodicities, we analyzed our samples with small and high angle x-ray scattering. Typical rocking widths for the Dy/Y have been found to about 0.5° which are larger

than for the superlattices grown in the $[0001]$ orientation. Unfortunately, the very high quality of the *c*-axis grown superlattices could not be completely reached in the superlattices grown along $[1\bar{1}02]$.

To illustrate the magnetic behavior we present the results of 3 superlattices and one 200 nm thick Dy layer grown in the same way as the superlattices. In the superlattices the Dy individual layer thickness was varied and the Y layer thickness was held nearly constant (see Table I). SQUID magnetometry and neutron diffraction measurements were used to analyze the superlattices and the Dy layer. Figure 1 shows a typical zero field cooled SQUID measurement at a magnetic field of 100 Oe. The data show a peak at 95 K that indicates the occurrence of a ferromagnetic phase. An additional peak at 170 K reflects the Néel temperature T_N of the helical magnetic phase. The SQUID data of the 200 nm thick Dy show a behavior close to bulk Dy with the first peak at 85 K (ferromagnetic Curie temperature) and a second peak due to the Néel temperature at 188 K. Field cooled measurements in the 200 nm thick Dy layer confirm that the phase transition to the ferromagnetic phase is more gradual than the first-order transition in bulk. For the superlattices the ferromagnetic peak was found at slightly higher temperatures than for the 200 nm thick Dy layer (see Table I), and the second (helical antiferromagnetic) peak was found at lower temperatures than in bulk which decrease with decreasing Dy layer thickness (see Table I).

The neutron diffraction measurements were performed at the Research Reactor Center of the University of Missouri-Columbia. Neutron data were taken on a triple-axis spectrometer using 2.35 Å wavelength neutrons from a silicon monochromator and (002) pyrolytic graphite analyzer. Slit collimators with 54'–40'–40'–40' acceptance angles were used before and after the monochromator and analyzer, respectively. The *c*-axis of the superlattices which has an angle of 42.2° to the out-of-plane $[11\bar{2}0]$ film orientation was oriented parallel to the scattering vector. This configuration allowed continuous scans in *Q* along the $(000l)$ orientation, which is also the propagation direction of the incommensurate helimagnetic order.

On both sides of the (0002) nuclear peak we found magnetic peaks caused by the helical antiferromagnetism in all

TABLE I. Results of SQUID and neutron diffraction measurements.

Sample	SL individual layer thicknesses (in monolayers)	SQUID: 1.peak	SQUID 2.peak	Neutron diffraction: max. temperature for magnetic peaks
SL A	[Dy ₃₃ /Y ₁₅] ₃₀	100 K	175 K	175 K
SL B	[Dy ₂₁ /Y ₂₀] ₃₄	95 K	170 K	165 K
SL C	[Dy ₉ /Y ₁₇] ₃₀	95 K	150 K	150 K
Dy layer	200 nm Dy	85 K	188 K	not measured

samples (see Fig. 2 for superlattice A). In the case of superlattice C with a 9 ML thick Dy layer thickness these peaks were very weak. Figure 3 shows the temperature dependence of the average turn angle of the helimagnetic spiral weighted between Dy and Y layers, found from the (0002)[±] peak positions. The behavior is very much like the samples grown in [0001] orientation. In the superlattices the helimagnetic phase is observed down to 10 K. The turn angles show an almost linear behavior above 100 K but lock into constant values below 100 K. With decreasing Dy layer thickness the turn angles were larger. This particular behavior is expected because the nominal Y turn angle is larger than that of Dy. We could not extract the turn angles of the Dy layers separately because of the different orientations of the superlattice periodicity and the magnetic propagation axis and furthermore because of the lack of superlattice harmonics on one side of the helimagnetic peaks. The turn angles of the thick Dy are similar to bulk behavior and exhibit a lower turn angle than for the superlattice. In the case of the thick Dy layer no helimagnetic phase peaks were found below the Curie temperature.

For the superlattices with the thicker Dy layers (superlattice A and superlattice B) the magnetic satellite peaks show harmonics (only one side can be distinguished in the data of Fig. 2) due to the superlattice periodicity. Since we have grown the superlattices in [1102] orientation but the scan is along [0001], we observe only the projection of the superlattice periodicity on the magnetic peaks in the [0001] orientation. To show that the superlattice harmonics of the magnetic peaks have their maxima in orientations parallel to [1102], we carried out additional scans along $[\delta \delta 0 \ l+2\delta]$

FIG. 1. Zero field cooled SQUID measurement for the superlattice [Dy₂₁/Y₂₀]₃₄ (superlattice B). The measurement was performed with increasing temperature from 10 K at a magnetic field of 100 Oe.

across the magnetic peaks (area scans). The insets of Fig. 2 present such scans. The scans cross the [0001] axis at $l=1.822$ ($Q_l=2.018 \text{ \AA}^{-1}$, (0002)⁻ peak) and at $l=2.171$ ($Q_l=2.426 \text{ \AA}^{-1}$, (0002)⁺ peak). The superlattice harmonics are clearly resolved in these measurements and their Q separation agrees with our measured superlattice periodicity.

Aside from the orientational effects on the harmonics of the (1102)Dy/Y superlattices the neutron results for the helimagnetism are qualitatively similar to the (0002)Dy/Y superlattices. However, the spin coherence range is much more restricted. The coherence lengths of the helimagnetic spirals vary for the (1102) superlattices from 12.0 to 24.0 nm. Taking into consideration the superlattice periodicity and its projection to the [0001] orientation, these values for the coherence length are equivalent to about two periods of each (Dy/Y) superlattice in the [0001] orientation.

More striking, however, is the simultaneous observation of a ferromagnetic phase in the (1102) superlattices that was not seen in (0002) superlattices. Additional (0002) peak intensity was found below room temperature in superlattices A and B reflecting this ferromagnetism. This is shown in Fig. 4 for superlattice A where we plot the square root of the excess integrated intensity of the (0002) peak normalized by the nuclear-only intensity. This value is proportional to the ferromagnetic moment component. The figure also shows the

FIG. 2. Neutron diffraction scan along [000 l] direction in [Dy₃₃/Y₁₅]₃₀ (superlattice A). The measuring temperature was 100 K. The solid line represents a fit to the data using a Voigt function for the (0002) nuclear peak and Gaussians for the (0002)[±] magnetic peaks. The split of the [000 l] magnetic peaks is caused by the superlattice harmonics which have their maxima in an orientation parallel to the growth direction (only one side of the harmonics can be distinguished). The insets show neutron diffraction scans across the (0002)⁻ and (0002)⁺ magnetic peaks in orientations parallel to the growth direction. The scans are along the $[\delta \delta 0 \ 1.822+2\delta]$ and the $[\delta \delta 0 \ 2.172+2\delta]$ orientations at $Q_l=2.018 \text{ \AA}^{-1}$ and $Q_l=2.426 \text{ \AA}^{-1}$, respectively.

FIG. 3. Temperature dependence of interplane turn angles of the helimagnetic spiral for superlattice $[Dy_{33}/Y_{15}]_{30}$. The values are weighted averages of the turn angles of the Dy and the Y layers.

square root of the total integrated intensity of the helimagnetic satellite peaks again normalized to the intensity of the (0002) peak above T_N .

Dy/Lu(0002) superlattices⁶ also show ferromagnetic order. Lu is a spacer material that compresses the Dy basal plane (2.4% lattice mismatch), favoring ferromagnetism, as opposed to the large Y lattice that favors helimagnetism. In the $(1\bar{1}02)$ Dy/Y superlattices one a-axis must be found in the film plane and should undergo an expansion similar to that in the (0002)Dy/Y superlattices. However, the other two a-axes do not lie in the film plane and undergo a different expansion due to the anisotropic lattice strain epitaxy. This may be the mechanism responsible for the mixed magnetic behavior in the $(1\bar{1}02)$ superlattices A and B.

In conclusion we have grown $(1\bar{1}02)$ Dy/Y superlattices and found a coexistence of a helimagnetic phase and a ferromagnetic phase. The average turn angles measured down to 10 K are similar to (0002)Dy/Y superlattices. The coher-

FIG. 4. Temperature dependences of the magnetic peak relative intensities. The solid circles represent the ferromagnetic moment component derived from the square root of the excess integrated intensities of the (0002) peak at different temperatures normalized by its average value above T_N . The open circles represent the helimagnetic component derived from the square root of the integrated intensity of the $(0002)^-$ and the $(0002)^+$ helimagnetic satellites normalized to the (0002) nuclear peak intensity.

ence length of the helimagnetic spiral was limited to about two superlattice periods. In the $[Dy_9/Y_{17}]_{30}$ superlattice with a thin Dy layer thickness separated by thick Y spacers only the helimagnetic phase was observed.

Utilizing the magneto-optic Kerr effect (MOKE) in conjunction with x-ray and neutron reflectometry (NR) and diffraction, we have studied the magnetic coupling of Fe/Cr(001) superlattices grown at room temperature and 250 °C. Only the samples grown at elevated temperature exhibit noncollinear coupling of 5.0 nm Fe layers across 1.7 nm Cr interlayers. The noncollinear samples feature a less-disordered in-plane interfacial structure than those grown at room temperature. Using x-ray diffuse reflectivity, we have measured a length scale of 10 nm for these in-plane features. We have also observed, via NR, a remanent noncollinear coupling angle of 50° and, via MOKE and NR, a gradual approach to saturation at upwards of 7 kOe. These features can be explained qualitatively by the proximity magnetism model of Slonczewski. We will compare the predictions of both the proximity and bilinear/biquadratic models with our data and present the results of ongoing neutron measurements of the temperature dependence of the coupling. © 1996 American Institute of Physics. The structural, electronic, and magnetic properties of the 2Pt/5Fe/2Pt(111) system were investigated using the total energy full-potential linearized augmented-plane-wave method. The interplanar relaxation, determined by the atomic force approach, was found to be large between the nearest Pt-Fe and Fe-Fe distances, thus altering the electronic and magnetic properties of the system. We find an enhancement of the spin and orbital Fe magnetic moment ($2.44 \mu_B$) at the interface, and a large induced magnetic moment ($0.27 \mu_B$) at the interfacial Pt site, which is relatively short ranged. The effects of the interface on the contact hyperfine fields is evaluated: The (negative) core-polarization contribution is found to scale with the moment, but the valence contribution changes from negative in the interior to *positive* at the interface. The trend of the calculated layer-by-layer hyperfine fields agrees well with experiment. © 1996 American Institute of Physics. [S0021-8979(96)51408-X]

I. INTRODUCTION

Recent experiments have revealed that (Co,Fe)/(Pd,Pt) multilayers where the ferromagnetic layers are only a few monolayers thick show perpendicular magnetic anisotropy; combined with the large magneto-optical Kerr rotation, these multilayers appear to be promising candidates for high-density magneto-optical storage media.^{1,2} It is well known that Pd and Pt are considered to be "nearly magnetic" with anomalously large susceptibility. A small percentage (0.1 at. %) of Fe in bulk Pd induces magnetic moments on the surrounding Pd atoms giving rise to giant magnetic moments of $10 \mu_B$ per Fe atom. Similarly, Pd or Pt atoms at an Fe/Pd or Fe/Pt interface are strongly polarized by the Fe atoms.^{3,4} Magnetization measurements on Fe/Pt multilayers have shown an enhanced magnetization by about 15% over the bulk Fe value for Fe thicknesses larger than 12 \AA .¹⁵ Recent magnetization and Mössbauer measurements⁶ on Fe/Pt multilayers have shown a strong enhancement of about 15% of the hyperfine field in the second Fe monolayer below the interface, which fades out in a damped oscillation within 6–10 Fe monolayers. A similar trend of the layer-by-layer hyperfine field was observed for the Fe/Pd multilayers.⁷

In order to understand the changes in electronic structure induced at the Fe/Pt interface, and their effects on modifying the atomic magnetic moments and hyperfine fields as compared to the corresponding bulk values, we have carried out a series of self-consistent spin-polarized local-spin-density total energy calculations with the use of the full-potential linearized augmented-plane-wave (FLAPW) method.⁸ Because of the high density of states at the Fermi level in Pt and the sensitivity of the number of the Fe majority spin holes on the local environment,³ structural changes should reflect themselves in the magnetic response of the Fe and Pd atoms near the interface and in the interlayer magnetic coupling. Thus a well determined atomic structure is always a prerequisite for obtaining reliable predictions of the electronic and magnetic properties—especially for those systems with strong overlayer–substrate hybridization.

II. COMPUTATIONAL METHOD AND RESULTS

In this article, the structural properties of the 2Pt/5Fe/2Pt(111) sandwich were determined using the atomic force approach,⁹ which yields a well-optimized atomic structure. The Pt/Fe(111) system is simulated by a slab consisting of five layer of Fe and two layers of Pt on each side. We have carried out two sets of electronic structure calculations with the in-plane lattice constant frozen to either that of bulk fcc Pt ($a_{\text{Pt}}=5.243 \text{ a.u.}$) or to the value of $a=5.063 \text{ a.u.}$, which is about the average of the bulk Fe and Pt interatomic distances. The interplanar distances of *all* layers in the slab are adjusted efficiently according to the calculated forces.⁹ In the FLAPW approach, no shape approximations are made to the charge densities, potentials, and wave functions. The Kohn–Sham equations are solved self-consistently with an energy cutoff of 13 Ry for the variational plane-wave basis set. Within the muffin-tin spheres ($r_{\text{Fe}}=2.15 \text{ a.u.}$ and $r_{\text{Pt}}=2.45 \text{ a.u.}$), lattice harmonics with angular momentum l up to 8 are employed to expand the charge density, potential, and wave functions. Summations over 18 k points in the $\frac{1}{12}$ irreducible 2D Brillouin zone are employed for k -space integrations. When the mean-root-square difference between the input and output charge and spin densities in the semirelativistic iterations is converged to better than $1.0 \times 10^{-4} e/(\text{a.u.})^3$, the spin–orbit coupling is invoked as a perturbation in a second variational way.¹⁰

Calculated results for the layer-by-layer vertical atomic positions, spin and orbital magnetic moments, and Fermi contact hyperfine fields broken down into valence ($H_{\text{CF},v}$) and core contributions $H_{\text{CF},c}$ are listed in Table I, for the two values of the in-plane lattice constant. The structure with the bulk fcc Pt in-plane lattice constant is found to be the most stable (lowest total energy). Large multilayer relaxations are found for the Pt–Fe and Fe–Fe interplanar distances which play an important role on the electronic and magnetic properties of the system. The interlayer Fe–Fe distance, 3.26 a.u. in the interior region and 3.23 a.u. in the interfacial region, is much smaller than the corresponding Pt–Pt interlayer dis-

TABLE I. Calculated layer-by-layer vertical atomic positions, z (in a.u.), spin and orbital magnetic moments, M and L_z (in μ_B), Fermi contact hyperfine fields H_{CF} broken down into valence ($H_{CF,v}$) and core ($H_{CF,c}$) contributions (in kG), and the ratios $H_{CF,c}/M$ in (kG/ μ_B) for Fe/Pt(111), for two values ($a=5.243$ a.u. and $a=5.063$ a.u.) of the in-plane lattice constant.

Atom	Fe(C)	Fe(I-1)	Fe(I)	Pt(I)	Pt(S)
$a=5.243$ a.u.

tance of 4.28 a.u. in bulk fcc Pt. This is expected, of course, since the size of Fe atoms is much smaller than that of Pt atoms. Nevertheless, the Fe-Fe interatomic distance of 4.45 a.u. is still smaller by about 5% than that of 4.69 a.u. in bcc Fe. This shrinkage of the Fe-Fe distance can be attributed (i) to interfacial effects and (ii) to the failure of the local density approximation (LDA) imposed on the density functional

FIG. 1. Calculated charge and spin densities for Pt/Fe(111). Contours start from $\pm 1 \times 10^{-3} e/a.u.^3$ and increase successively by a factor of $\sqrt{2}$. Solid (dotted) lines in (b) denote the positive (negative) spin density, respectively.

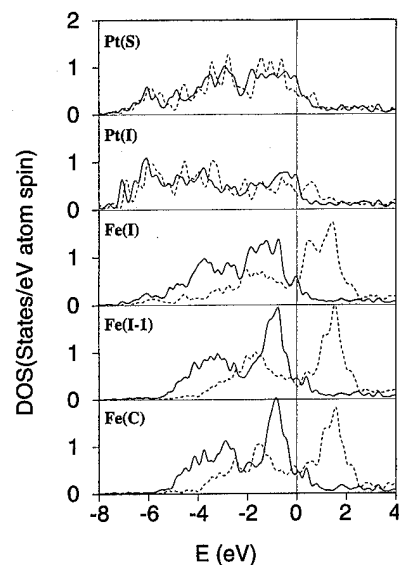

FIG. 2. Calculated layer-by-layer density of states for Pt/Fe(111). Solid and dashed lines stand for majority and minority spin parts, respectively. Energies are measured with respect to the Fermi energy.

theory which is known for underestimating the lattice constants of 3d transition metals by about 3%.¹¹ Note that while there is, as expected, an expansion of the interlayer distances for the smaller (5.063 a.u.) in-plane lattice constant, the Fe-Fe interatomic distance remains almost intact (within 1%). For both sets of calculations, the Pt-Fe and Pt-Pt interatomic distances are 4.65 and 5.22 a.u., respectively. These results clearly indicate that metal atoms tend to preserve their volumes upon slight changes of local environment. Surprisingly, while the Pt-Fe distance shrinks by 6.5% compared to the average of the bond lengths in bulk Fe and Pt, no relaxation ($<1\%$) is found between the Pt-Pt layers, despite the presence of the surface and the interface on either side of the Pt layers.

The charge density of the Pt/Fe(111) is presented in Fig. 1(a). The charge density in the interfacial region between Fe and Pt is greater than that between Pt and Pt atoms, indicating a strong Fe-Pt bonding. The strong interfacial interaction between the magnetic Fe overlayer and the Pt substrate can be seen more clearly in Fig. 2, where the layer-by-layer density of states (DOS) of the majority and minority spin are plotted. The profile of the DOS of the interface Fe(I) atom differs substantially from that of the central Fe(C) atom and even from that of the subinterface Fe(I-1) atom. Strong hybridization can be seen especially in the energy range of -6 to -4 eV and around the Fermi level for the majority spin, and around +1 eV and below -4 eV for the minority spin. As a result, the 5d bands of the interface Pt(I) and even of the surface Pt(S) are spin polarized. Note also that the d bands of the interfacial Fe(I) and Pt(I) layers are broadened, corresponding to the strong overlayer-substrate hybridization.

The spin density of the Pt/Fe(111) is shown in Fig. 1(b). The solid (dashed) lines label the positive (negative) contours. We find that (i) the Fe layers adopt ferromagnetic coupling in the distorted fcc structure; (ii) the induced magnetism

zation of the Pt(*I*) site is parallel to that of Fe; and (iii) the magnetic disturbance in the Pt layers is short ranged [the volume associated with the positive spin density around Pt(*S*) becomes very small]. As can be seen more quantitatively in Table I, the spin magnetic moments of the Fe(*C*) and Fe(*I*-1) are 2.07 and 2.11 μ_B , respectively. These values are well below the calculated magnetic moment of 2.25 μ_B for bcc bulk Fe using the experimental lattice constant ($a=5.425$ a.u.), but close to that of 2.06 μ_B obtained using the LDA optimized lattice constant ($a=5.225$ a.u.). By invoking the spin-orbit coupling, small orbital magnetic moments, 0.03 and 0.05 μ_B , are found for the Fe(*C*) and Fe(*I*-1), respectively. From the DOS curves in Fig. 2, we see that there is a smaller number of majority spin *d* holes for the Fe(*I*) atom compared to that for the other Fe atoms. As a result, there is an enhancement of the Fe(*I*) magnetic moment (2.44 μ_B), which indicates the important role of the Pt-Fe interfacial hybridization on the Fe magnetization. The orbital magnetic moment of the Fe(*I*) is also found to be large, 0.1 μ_B . It is desirable to have experimental measurements using the magnetic circular dichroism technique to verify our theoretical predictions. The magnetic perturbation in the Pt layers is a shorter range effect since the induced spin (orbital) moment decreases quickly from 0.27 (0.08) μ_B in the Pt(*I*) layer to 0.05 (0.01) μ_B in the surface Pt(*S*) layer. It is important to note that the magnetic moments listed in Table I for the two values of the lateral lattice constants differ markedly, even though the interatomic distances remain almost unchanged. Clearly, this shows that the magnetism in Pt/Fe(111) is very sensitive to the details of the geometry, and thus a well-optimized atomic structure appears to be very important.¹²

The magnetic hyperfine interaction, which describes the interaction of the electronic spin moment with the nuclear magnetic moment, provides an important tool for the study of interface magnetism. Table I presents the calculated layer-by-layer Fermi contact hyperfine fields broken down into valence and core contributions. As established for many magnetic systems,³ the core contribution (negative in sign) is proportional to the local Fe magnetic moment. The ratio of the core-hyperfine-field and the magnetic moment (137.5 kG/ μ_B) is independent of the value of the in-plane lattice constant, and is very close to that obtained for other systems, 130–140 kG/ μ_B .³ While our results for the Fe(*I*) layer do show an enhancement of the interfacial magnetic moment, the total calculated H_{CF} is smaller in magnitude (–275 kG) due to the large positive (+60 kG) valence contribution,

which, however, is localized to the interface; the subinterface valence contributions are again negative. Thus, as in previous calculations,³ we find that while the core contribution is dominant, the valence contribution is very sensitive to the local environment. The trend of the calculated layer-by-layer H_{CF} agrees well with recent Mössbauer experiments;⁶ i.e., the total H_{CF} is relatively smaller at the Fe(*I*), increases by 8.5% at the Fe(*I*-1), and then decreases again by 4% at the Fe(*C*). However, due to the small Fe-Fe interlayer distances found in our calculations, the results for the total hyperfine fields and magnetic moments are about 8%–10% smaller than the measured values.¹²

Magnetic properties and magnetization reversal in Co/Au multilayers (abstract)

Z. S. Shan, J. X. Shen,^{a)} R. D. Kirby, and D. J. Sellmyer

Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0113

We report studies of magnetic properties in Co X Å/Au60 Å multilayers ($X=5,6,7,8,12,20$ Å), which were prepared by sputtering on Si(111) substrates, with emphasis on the magnetization reversal. Magnetization reversal was investigated by measurements of initial magnetization curves, minor loops, coercivity as a function of the maximum field of minor loops, temperature dependence of magnetic properties using Kronmüller's model,¹ time decay of Kerr rotation angle Θ_K , and the field-sweep speed dependence of coercivity $H_c(dH_a/dt)$ at room and/or low temperature. It is found that (1) the thermal activation volumes determined by $H_c(dH_a/dt)$ increase from $\sim 2.0 \times 10^{-17}$ to $\sim 9.9 \times 10^{-17}$ cm³ as X varies from 5 to 20 Å, which corresponds to a cylindrical activation volume with ~ 800 Å diameter. (2) A Kronmüller analysis together with the initial magnetization curves, etc., for a Co5 Å/Au60 Å sample at room and low temperature indicates that wall pinning with small pinning sites is the major coercivity mechanism. The interaction between grains was studied with the so-called ΔM method: samples with thin Co layers ($X=5,6,7$ Å), which show perpendicular anisotropy, exhibit negative ΔM or dipolar interactions, while samples with a thick Co layer (e.g., $X=20$ Å), which show in-plane anisotropy, exhibit positive ΔM or ferromagnetic exchange interactions. © 1996 American Institute of Physics. A sequence of fcc, $\langle 100 \rangle$ oriented, $[\text{Co} (50 \text{ \AA})-\text{Cu} (X)]$ superlattices with $X=25-200 \text{ \AA}$, was grown by molecular beam epitaxy on $\text{Cu}(100)/\text{Si}(100)$ substrates. In-plane 33.4 GHz ferromagnetic resonance (FMR) data were analyzed to determine the perpendicular uniaxial magnetic anisotropy field (H_u) and cubic anisotropy field contributions. The H_u values were found to be negative, indicating that the film normal is a magnetic hard axis. The magnitude of H_u depended on the Cu layer thickness. Superlattice x-ray-diffraction and reflection high-energy electron-diffraction patterns were analyzed. The measured strain data for Co superlattice layers, in combination with known elastic and magnetostriction constants for bulk fcc Co, yield calculated strain-induced H_u values which agree well with those obtained from the FMR. The observed H_u values, which are affected by the Cu layer thickness, approach a constant for Cu thickness $>100 \text{ \AA}$. © 1996 American Institute of Physics. [S0021-8979(96)51508-6]

INTRODUCTION

We report here our coordinated strain-dependent magnetic anisotropy studies of Co-Cu (100) superlattices using reflection high-energy electron diffraction (RHEED), x-ray diffraction (XRD), and ferromagnetic resonance (FMR). Many phenomena observed in magnetic multilayers are strongly affected by structural and interfacial perfection of the films and the presence of strains.¹ Recently we studied strained Ni-Cu(100) superlattices of varying Ni and Cu layer thicknesses using in-plane and out-of-plane FMR.² The observed uniaxial perpendicular magnetic anisotropy was found to be solely strain induced and depended not only on the layer thickness of Ni but also on that of Cu. In 1968 Jesser and Matthews³ used transmission electron microscopy studies to show that ultrahigh vacuum evaporated deposits of Co on a (001) Cu surface at room temperature have fcc structures and are elastically strained so as to match the Cu lattice across the Co-Cu interface. For Co film thicknesses larger than 20 Å long dislocations were generated to accommodate part of the difference between the lattice parameters of fcc Co and Cu. Jesser and Matthews observed an increase in the density of misfit dislocations as the thickness of Co film was further increased. Heinrich *et al.*,⁴ using FMR, have investigated magnetic anisotropy in ultrathin films of metastable fcc Co(001) films grown on a bulk Cu(001) single crystal and covered by a Cu(001) film. A large negative uniaxial perpendicular anisotropy field was observed, a consequence of the tetragonal distortion induced in a Co(001) lattice grown on Cu(001).

EXPERIMENT

A sequence of Co-Cu (100) superlattices was prepared in an ultrahigh vacuum using a molecular beam epitaxy deposition system with a base pressure $<1 \times 10^{-10}$ Torr. The superlattices were grown on a 1200 Å thick Cu(100) seed layer deposited on Si(100) substrates etched with a 10% hy-

drofluoric acid solution. Co and Cu were evaporated from two independent electron-beam evaporators with computer-controlled pneumatic shutters and at deposition rates of $\sim 0.5 \text{ \AA/s}$. Further details of the deposition system, the growth of Cu(100) seed layers on hydrogen-terminated Si(100), and the growth of epitaxial Co(100) layers on Cu(100) layers are described elsewhere.^{5,6} In order to determine the effect of the Cu thickness on the strain and magnetic anisotropy, four different superlattices were prepared, each with a constant Co layer thickness of 50 Å alternated with Cu layers of thicknesses of 25, 50, 100, and 200 Å, respectively. The total thickness of Co in each superlattice was kept at 500 Å. All films had a 50 Å Cu cap layer for protection from oxidation.

During the deposition of the film, RHEED scans were continuously recorded (up to 30 scans per second) using a CCD camera. RHEED scans were subsequently analyzed to determine the in-plane strains of the superlattice layers. Standard $\theta-2\theta$ XRD scans were performed with Cu $K\alpha$ radiation. A one-dimensional x-ray scattering model, which includes discrete layer thickness fluctuations and interface diffusion in the kinematic approximation, was used to determine the periodicity of the superlattice as well as the strains in the Co and Cu layers.⁷

RESULTS AND DISCUSSION

Sharp and elongated spotty RHEED patterns were observed during the growth of all Co-Cu superlattice films indicating epitaxial but three-dimensional growth. The full fourfold azimuthal symmetry of the $\langle 100 \rangle$ orientation for the Co-Cu superlattices was clearly observable for all the films. The mismatch between the Cu and fcc Co bulk value lattice spacings (3.617 and 3.548 Å, respectively) is 1.9%. This is small enough that strained, epitaxial growth can be anticipated for the Co-Cu superlattice films. Figure 1 shows the in-plane lattice spacings, d_{200} , obtained from the recorded horizontal line scans of the RHEED pattern observed during the growth of first two bilayers of a $[\text{Co}(50 \text{ \AA})-\text{Cu}(200 \text{ \AA})]$

FIG. 1. In-plane lattice spacings of Co and Cu layers obtained from RHEED scans during the growth of first two bilayers of the $[\text{Co}(50 \text{ Å})\text{-Cu}(200 \text{ Å})]$ superlattice. The solid line is only a guide to the eyes.

superlattice grown on a 1200 Å thick Cu(100) seed layer deposited on a Si(100) substrate. The data indicate that the Co lattice is initially stretched to match the bulklike Cu lattice but relieves its strain, perhaps by formation of dislocations.³ It is interesting to note that the Co lattice remains stretched at a thickness of 50 Å with a residual in-plane strain of $\sim 0.6\%$. Further growth of Cu on Co shows that the Cu lattice initially gets compressed to match the Co lattice and then approaches bulk Cu lattice spacing for a Cu thickness ~ 100 Å. Hence, for superlattices with Cu layer thicknesses < 100 Å, it is expected that Co and Cu layers are coherently strained and that the strain in Co layers is affected by the Cu layer thickness. Figure 2 shows the lattice spacings, d_{200} , of Co and Cu layers during the growth of the first three bilayers of a $[\text{Co}(50 \text{ Å})\text{-Cu}(50 \text{ Å})]$ superlattice. The Co layers in the second and third bilayers are strained to a lesser extent compared to the first Co layer which is grown on a bulklike Cu seed layer. These results correlate with XRD measurements as explained below.

FIG. 2. In-plane lattice spacings of Co and Cu layers obtained from RHEED scans during the growth of first three bilayers of the $[\text{Co}(50 \text{ Å})\text{-Cu}(50 \text{ Å})]$ superlattice. The solid line is only a guide to the eyes.

FIG. 3. (a) The high-angle XRD scan for the $[\text{Co}(50 \text{ Å})\text{-Cu}(100 \text{ Å})]$ superlattice. Simulations of the XRD intensities for this superlattice (b) with bulk Co(200) and Cu(200) lattice spacings of 1.774 and 1.808 Å; (c) and with Co(200) and Cu(200) lattice spacings of 1.747 and 1.815 Å.

High-angle x-ray-diffraction measurements on all of the samples confirm $\langle 100 \rangle$ oriented growth of the Co-Cu superlattices with no trace of the $\langle 111 \rangle$ texture. Figure 3(a) shows the XRD scan for a Co-Cu superlattice with a Co layer thickness of 50 Å and a Cu layer thickness of 100 Å. Comparisons of the simulated XRD patterns to the observed peak patterns for the Co-Cu superlattices indicate a strong dependence upon the lattice spacing modulations and a relative insensitivity to composition modulations, very similar to the observations on Ni-Cu(100) (see Ref. 3) and Co-Cu(111) (see Ref. 7) superlattices. Figure 3(b) shows the simulated XRD intensities for the above superlattice with bulk Co(200) and Cu(200) lattice spacings of 1.774 and 1.808 Å, respectively. Obviously, these simulated XRD intensities do not reproduce the experimental pattern. On the other hand, Fig. 3(c) shows the simulated XRD intensities for strained Co(200) and Cu(200) lattices with spacings of 1.747 and 1.815 Å, respectively. Although we use a single average value for the lattice spacing for each component of the superlattice (contrary to the RHEED observations), Fig. 3(c) represents a reasonable simulation of the experimental XRD pattern. The $d_{\perp} (= d_{200})$ spacings for both Co and Cu in these superlattices are determined from the best fit of the simulations to the experimental XRD data (see Table I) and clearly show that the Co lattices are contracted while the Cu lattices are dilated along the growth direction. This is consistent with the RHEED results since an expansion of the Co lattice in the direction parallel to the film plane leads to a contraction of the lattice perpendicular to it. The observed tetragonal distortion (see Table I) for Co amounts to a few percent as reflected by the negative values of $(\epsilon_{\perp} - \epsilon_{\parallel})$, where ϵ_{\perp} and ϵ_{\parallel} are the perpendicular and parallel strains, respectively. $\epsilon_{\perp} = (d_{\perp} - d_0)/d_0$ and ϵ_{\parallel} is evaluated using the relation

TABLE I. XRD and FMR results for Co-Cu(100) superlattices.

t_{Co} (Å)	t_{Cu} (Å)	Co d_{200} (Å)	Cu d_{200} (Å)	Co ($\epsilon_{\perp} - \epsilon_{\parallel}$) ^a	$4\pi M_{\text{eff}}$ (kG)	$2K_1/M_s$ (kOe)	H_u (FMR) ^b (kOe)	H_u (Calc.) (kOe)
50	25	1.757	1.827	-0.0168	22.0	-1.0	-3.7	-3.7
50	50	1.752	1.820	-0.0217	23.3	-1.1	-5.0	-4.8
50	100	1.747	1.815	-0.0266	23.6	-1.2	-5.3	-5.8
50	200	1.747	1.810	-0.0266	23.7	-1.2	-5.4	-5.8

^a $\epsilon_{\parallel} = -\epsilon_{\perp}(1-\nu)/2\nu$ where ν is the Poisson ratio. $\nu=0.4$ for fcc Co.

^b $H_u = 4\pi M_s - 4\pi M_{\text{eff}}$ where $4\pi M_s = 18.3$ kG for bulk fcc Co. H_u (Calc.) obtained from strain data. Uncertainties: $d_{200} \pm 0.002$, $(\epsilon_{\perp} - \epsilon_{\parallel}) \pm 0.0024$, $4\pi M_{\text{eff}} \pm 0.5$, $2K_1/M_s \pm 0.05$, H_u (FMR) ± 0.5 , H_u (Calc.) ± 0.6 .

$\epsilon_{\parallel} = \epsilon_{\perp}(1-\nu)/2\nu$, where d_0 is the undistorted Co spacing and the Poisson ratio $\nu=0.4$ for Co.⁴ Although the Co layer thickness is kept same (50 Å) in all the superlattices, we note that the tetragonal distortion of the Co lattice is sensitive to the Cu layer thickness.

The FMR data were taken at room temperature in a 33.4 GHz, TE₀₁₁ cylindrical cavity system. At this microwave frequency the requisite resonance magnetic field is sufficient to magnetically saturate the samples. Typical FMR samples were 2 mm×2 mm and were aligned along cleavage faces of the Si substrate. Resonance fields for in-plane FMR measurements on all films exhibit an oscillatory angular dependence with respect to a $\langle 100 \rangle$ crystallographic direction in the film reflecting the fourfold symmetry of the Co layers. From fits to the angular dependence⁵ of the experimental resonance data, the effective demagnetization field $4\pi M_{\text{eff}}$ and the cubic anisotropy contribution $2K_1/M_s$ are determined (see Table I) where K_1 is the fourth-order cubic anisotropy constant and M_s is the saturation magnetization. The presence of any perpendicular magnetic anisotropy H_u can be numerically determined from the relationship $H_u = 4\pi M_s - 4\pi M_{\text{eff}}$. The bulk Co values of $g=2.13$ and $4\pi M_s = 18.3$ kG have been utilized in the calculations.^{8,9}

Utilizing the measured strain $(\epsilon_{\perp} - \epsilon_{\parallel})$ from XRD data, we have calculated the contribution to the strain-induced magnetic anisotropy due to inverse magnetostriction using the following expression:¹⁰

$$H_u = (3/M_s)\lambda_{100}(C_{11} - C_{12})(\epsilon_{\perp} - \epsilon_{\parallel}). \quad (1)$$

Here λ_{100} is the linear magnetostriction constant along $\langle 100 \rangle$, and C_{11} and C_{12} are the cubic elastic constants. For bulk fcc Co values of^{4,9} $M_s = 1460$ emu/cm³, $\lambda_{100} = 1.3 \times 10^{-4}$, $C_{11} = 2.42 \times 10^{12}$ dyn/cm², and $C_{12} = 1.6 \times 10^{12}$ dyn/cm², Eq. (1) gives H_u values between -3.7 and -5.8 kOe for the

superlattices; see Table I. The magnitude of H_u depends on the Cu layer thickness and approaches a constant value for Cu thickness >100 Å. These values agree reasonably well with the values derived from FMR measurements. We note that the observed values of $2K_1/M_s$ for Co-Cu superlattices are similar to those of single-layered Co(100) samples.⁴

In summary, our coordinated studies on Co-Cu (100) superlattices using RHEED, XRD, and FMR measurements have shown that the strain in the Co lattice is affected by the thickness of Cu layers and that magnetostriction plays a significant role in determining the magnetic anisotropy. The observed H_u values depend on the Cu layer thickness and approach a constant for Cu thickness >100 Å.

Co(1100)/Cr(211) and Co(1120)/Cr(100) multilayers have been simultaneously prepared on MgO(110) and MgO(100) substrates, respectively, by molecular beam epitaxy. They show however distinct magnetic anisotropic behavior which coincides with their magneto-crystalline anisotropy. Magneto-optical Kerr effect shows the existence of a unique easy axis and strong in-plane uniaxial magnetic anisotropy in Co(1100)/Cr(211) multilayers, which is induced by the well-defined hexagonal crystalline of the Co(1100) layers. For Co(1120)/Cr(100) multilayers, on the other hand, an in-plane biaxial magnetic anisotropy is found due to the bicrystalline structure of the Co(1120) layers. © 1996 American Institute of Physics. [S0021-8979(96)51608-X]

I. INTRODUCTION

The magnetism of thin metallic films and multilayers has attracted much attention in recent years for both fundamental research and advanced technological applications. It is noted that magnetism in these systems can often be characterized by specific magnetic anisotropies. For example, the perpendicular surface (interface) anisotropy can exist in ultra thin magnetic films (multilayers) as a consequence of symmetry breaking in the surface (interface).¹ There also has been an increasing interest in understanding the relationship between the magnetic anisotropies and the crystal structures. It is found that the magnetic anisotropies of the thin films may depend strongly on the underlying templates (substrates or buffer layers).²⁻⁵

Co-related system is suitable for studying the correlation between structure and magnetism owing to the abundance of the its structural and magnetic properties. The bulk phase of Co is known as hexagonal close packed (hcp) at room temperature. It undergoes a Martensitic structural transformation to face centered cubic (fcc) phase at $\sim 400^\circ\text{C}$.⁶ In the form of thin films it can also be epitaxially stabilized as body centered cubic (bcc) structure.⁷ Co/Cr multilayers are of our high interest because of the remarkable structural and magnetic properties, and possible applications in magnetic or magneto-optical recording. Previous studies⁸⁻¹¹ on Co/Cr multilayers have been, however, restricted to polycrystalline, textured, or semiepitaxial samples, making the understanding of the structural and magnetic properties and their interplay much difficult.

In this article we report the magneto-optical Kerr effect (MOKE) studies of the magnetic anisotropies of high-quality Co(1100)/Cr(211) and Co(1120)/Cr(100) multilayers grown by molecular beam epitaxy (MBE). Longitudinal and polar MOKE configurations were used to determine the magnetic easy and hard axes, and their connection with the crystal structures. We demonstrate here the novel control of the orientation and crystalline structure, and hence the magnetic anisotropies (uniaxial or biaxial) of Co layers by using proper crystal plane of the underlying Cr layers.

II. FILM PREPARATION AND MEASUREMENTS

We have indeed grown more than 30 samples of Co/Cr(211) and Co/Cr(100) multilayers. The results presented here mainly focus on the general and common features of these samples. The specific Co/Cr samples discussed here possess 17 bilayers periods with 40 Å Co and 20 Å Cr in each bilayer: $[\text{Co}(40\text{ Å})/\text{Cr}(20\text{ Å})]_{17}$. The Co/Cr(211) and Co/Cr(100) multilayers were simultaneously prepared on epitaxial grade MgO(110) and MgO(100) substrates, respectively. Details of the growth procedures were described elsewhere.¹⁴

The crystal structure and quality were characterized by reflection high-energy electron-diffraction (RHEED) and x-ray diffraction (XRD). The correlation between the structural and magnetic properties were investigated by MOKE technique. Polar (magnetization lies in the scattering plane and perpendicular to the film surface) and longitudinal (magnetization lies both in the scattering plane and the film surface) configurations of MOKE were employed to determine the out-of-plane and in-plane magnetization loops of the samples. The MOKE measurements were carried out at room temperature in a magnetic field H up to 2 kOe. Note that the penetration depth¹² of the (He-Ne) laser light for MOKE experiment is of $\sim 150\text{--}200\text{ Å}$, only top three Co/Cr bilayers (of the multilayers) can be probed by MOKE.

III. RESULTS AND DISCUSSIONS

For Co/Cr multilayers on grown Mo buffer layers on MgO(110) substrates studied here, we have determined the following orientational relationships (ORs):

$$\text{Co}(1\bar{1}00)\parallel\text{Cr}(211)\parallel\text{Mo}(211)\parallel\text{MgO}(110),$$

$$\text{Co}[11\bar{2}0]\parallel\text{Cr}[\bar{1}11]\parallel\text{Mo}[\bar{1}11]\parallel\text{MgO}[\bar{1}10],$$

$$\text{Co}[0001]\parallel\text{Cr}[0\bar{1}1]\parallel\text{Mo}[0\bar{1}1]\parallel\text{MgO}[001];$$

while on MgO(100) substrates the ORs are:

$$\text{Co}(11\bar{2}0)\parallel\text{Cr}(100)\parallel\text{Mo}(100)\parallel\text{MgO}(100),$$

$$\text{Co}[1\bar{1}00]\parallel\text{Cr}[011]\parallel\text{Mo}[011]\parallel\text{MgO}[010],$$

here mainly about their magnetic properties and the effect of crystal structure upon magnetic anisotropies, as investigated by MOKE.

Figure 1 and Fig. 2 display the schematic diagrams of the geometry and the unit cells of Co(1100)/Cr(211) and Co(1120)/Cr(100) multilayers, respectively. Although Co (hcp) and Cr (bcc) possess distinct bulk structures, Co(1100) and Cr(211) planes match extremely well in lattice parameters and symmetry (both are twofold). As illustrated in Fig. 1, the unit cell of Co(1100), $4.07 \text{ \AA} \times 2.51 \text{ \AA}$, matches perfectly with that of Cr(211), $4.07 \text{ \AA} \times 2.50 \text{ \AA}$. This provides us an opportunity to synthesize high-quality heterostructural superlattices. For Co(1120)/Cr(100) system, on the other hand, the unit cell of Co(1120), $4.07 \text{ \AA} \times 4.34 \text{ \AA}$, match poorly in

FIG. 4. The MOKE hysteresis loops for the Co(1120)/Cr(100) multilayer: (a) polar Kerr loop; (b)–(h) longitudinal Kerr loops as a function of the azimuthal angle η .

FIG. 5. (a) Saturation field H_s is shown as a function of the azimuthal angle ϕ for the Co(1100)/Cr(211) multilayer. (b) Coercive field H_c is plotted as a function of the azimuthal angle η for the Co(1120)/Cr(100) multilayer.

one direction (Co[1100]) with the rotated cell of Cr(100), $4.07 \text{ \AA} \times 4.07 \text{ \AA}$, where $4.07 \text{ \AA} (= \sqrt{2} \times 2.88 \text{ \AA})$ is the diagonal spacing of the original cell. Indeed, Cr(100) possesses fourfold crystal symmetry while Co(1120) has only twofold symmetry. The symmetry and lattice-spacing mismatches between Co(1120) and Cr(100) cells result in the bicrystalline structure of the Co(1120) layers. That is, the Co[0001] axis can be either parallel to the Cr[011] or Cr[01 $\bar{1}$].

Shown in Figs. 3(a) and 4(a) are the polar MOKE hysteresis loops of the Co/Cr(211) and Co/Cr(100) multilayers, respectively. It is clear that both multilayers are hard to be magnetized along the out-of-plane directions. For Co/Cr(211) sample, Figures 3(b)–3(h) show a series of in-plane magnetization loops as a function of the azimuthal angle ϕ , where ϕ is defined as the angle between the MgO[110] (||Cr[01 $\bar{1}$])||Co[0001]) axis (see Fig. 1) and the direction of the applied field. Similar measuring procedures of the MOKE hysteresis loops for Co/Cr(100) multilayers are displayed in Figs. 4(b)–4(h), where in this case the azimuthal angle η is the angle between the in-plane MgO[001] (||Cr[01 $\bar{1}$]) axis (see Fig. 2) and the direction of the field.

Although both multilayers are difficult to be magnetized along the out-of-plane directions, they show however quite distinct in-plane azimuthal anisotropies. For Co/Cr(211) sample, square hysteresis loops were observed from $\phi = 0^\circ$ (H ||Co[0001]) to 75° with gradual increase of the saturation field as the angle ϕ is turned (experimentally done by in-plane rotation of the sample with the field direction fixed). While continuously varying magnetization curves were observed for field along $\phi = 90^\circ$ (H ||Co[1120]), as shown in Figs. 3(b)–3(h). The saturation field H_s here is defined as the field when the magnetization is 90% saturated during magnetization reversal process. It is obvious that the magnetic hard axis lies in the (in-plane) Co[1120] direction perpendicular to the easy axis Co[0001] (see Figs. 1 and 3). Very similar hysteresis loops and saturation fields were found for field directed along the azimuthal angles ϕ and $(180 - \phi)$ [as well as $(\phi + 180)$ and $-\phi$], suggesting the existence of a uniaxial magnetic anisotropy for the Co/Cr(211) sample.

This can be clearly seen by plotting H_s as a function of the azimuthal angle ϕ , as shown in Fig. 5(a). The relatively large saturation fields of >500 Oe in the easy direction is likely resulted from the Cr spacer layers.¹⁶

For Co/Cr(100) sample, on the other hand, the in-plane magnetization loops are more complicated. As shown in Fig. 4(b), squarelike hysteresis loops were observed for $\eta = 0^\circ$. By turning the azimuthal angle η from 0° to 45° , the hysteresis loops shift from one type to another with gradual decrease of the coercive field. Similar hysteresis loops and coercive fields were found for field directed along the azimuthal angles η and $(90 - \eta)$. The MOKE patterns in Figs. 4(b)–4(h) repeat for η from 90° to 180° (and every other 90°). Figure 5(b) shows the coercive field H_c as a function of the azimuthal angle η . As can be determined from Fig. 5(b) and Figs. 4(b)–4(h), the easy axes are along $\eta = 0^\circ$ (||Cr[011]) and $\eta = 90^\circ$ (||Cr[01 $\bar{1}$]), and the hard axis along $\eta = 45^\circ$ (||Cr[010]) and $\eta = 135^\circ$ (||Cr[001]), indicating the existence of a biaxial magnetic anisotropy for the Co/Cr(100) sample. Note that the two magnetic easy axes (along Cr[01 $\bar{1}$] and Cr[011]) coincide with the Co[0001] axes of the bicrystalline Co layers, as discussed above.

Similar magnetic anisotropic properties mentioned above have been detected in single bilayer films of Co/Cr(100) and Co/Cr(211). Furthermore, we have observed relatively strong (weak) anisotropic effect in magnetoresistance measurements for the latter (former) case.¹⁵ It appears that the anisotropic effect dominates in the Co/Cr(211) multilayers, in marked contrast to the other multilayer systems which show stronger coupling effect and isotropic (and giant) magnetoresistance effect. The mechanism of magnetization reversal processes, including the minor loop behaviors, of the Co/Cr(211) and Co/Cr(100) films will be published in the forthcoming articles.

¹⁶We have observed a trend that H_s decreases with the decreasing of the Cr thickness for a fixed Co thickness in the multilayers. For pure Co films on MgO substrates, the measured saturation fields are of only ~ 50 – 100 Oe.

Reorientational transition of the magnetic anisotropy and antiferromagnetic coupling of Co/Cr(001) superlattices

Th. Zeidler, F. Schreiber, and H. Zabel

Experimentalphysik/Festkörperphysik, Ruhr-Universität Bochum, 44780 Bochum, Germany

We have measured the magnetic anisotropy of high quality Co/Cr(001) superlattices as a function of the Co thickness using the magneto-optical Kerr effect (MOKE) and a torsion magnetometer. The samples grown by molecular beam epitaxy exhibit a reorientational transition of the easy axis from in-plane for large Co thicknesses ($t_{\text{Co}} \geq 14 \text{ \AA}$) to out-of-plane for $10 \text{ \AA} \leq t_{\text{Co}} \leq 14 \text{ \AA}$ and back again to the in-plane orientation for $t_{\text{Co}} \leq 10 \text{ \AA}$. We provide evidence that this reorientational transition of the magnetization direction is due to a sign change of the interface anisotropy constant induced by a concomitant structural phase transition of the Co layers from hcp to bcc with decreasing Co layer thickness. We have observed antiferromagnetic alignment of the Co layer magnetization both for in-plane and perpendicular magnetic anisotropy. The first maximum of the antiferromagnetic interlayer interaction occurs at $t_{\text{Cr}} = 6 \text{ \AA}$, which is in a good agreement with the results for Fe/Cr(001). In order to theoretically describe the spin structure of the antiferromagnetic coupled multilayers we have performed absolute minima calculations of the angle dependent anisotropy energy. In contrast to trilayer systems we found highly asymmetric spin structures in the superlattices during the remagnetization process. © 1996 American Institute of Physics. [S0021-8979(96)51708-6]

One of the important issues in the field of magnetic superlattices is the investigation of magnetic interface anisotropies. The crystal structure of the superlattices and sharp interfaces are of crucial importance for understanding of these anisotropies. In Co/Cr(001) superlattices the Co layers exhibit a continuous structural phase transition from hexagonal close packed (hcp) to body centered cubic (bcc) with decreasing Co layer thickness.¹ Therefore the magnetic properties of Co/Cr(001) superlattices are expected to be strongly influenced by this structural phase transition. The ideal bcc structure is, however, never realized even down to $t_{\text{Co}} = 5 \text{ \AA}$. Furthermore, concerning the oscillatory interlayer exchange coupling and the appertaining spin structure, a comparison between the similar systems Co/Cr(001) and Fe/Cr(001) is highly interesting.

The magnetic anisotropy as measured via magneto-optical Kerr effect (MOKE) hysteresis curves [Figs. 1(a) and 1(b)] and ferromagnetic resistance (FMR) (Ref. 2) for Co thicknesses $t_{\text{Co}} \geq 14 \text{ \AA}$ exhibits a typical $1/t_{\text{Co}}$ behavior indicating the presence of a perpendicular interface anisotropy in Co/Cr(001) superlattices with an extrapolated critical Co thickness $t_{\text{C}} \approx 13.5 \text{ \AA}$ for perpendicular magnetic anisotropy.³ From the slope we obtain an interface anisotropy constant of $K_{\text{S}} \approx -0.65 \text{ mJ/m}^2$ using the reduced value of magnetization $M_{\text{S}} = 1000 \text{ kA/m}$ as determined by a Faraday balance. This rather large value of K_{S} is comparable with results for Co/Pd and Co/Pt.^{4,5} The reduced magnetization M_{S} arises from a small interdiffusion zone at the interface between adjacent Co and Cr layers which is estimated to be $< 2 \text{ \AA}$.

The magnetic anisotropy energy per Co unit volume E_{A} of the system Co/Cr(001) can be expressed as

$$NE_{\text{A}} = \sum_{n=1}^N \frac{1}{2} \mu_0 M_{\text{S}}^2 \cos^2 \theta_n - \sum_{n=1}^N \mu_0 M_{\text{S}} H \cos(\theta_n - \theta_{\text{H}}) + \sum_{n=1}^N K_1 \cos^2 \theta_n + \sum_{n=1}^N K_2 \cos^4 \theta_n + \sum_{n=1}^N \frac{1}{t_{\text{Co}}} 2K_{\text{S}} \cos^2 \theta_n, \quad (1)$$

including Zeeman energy, shape anisotropy, crystal anisotropy terms of Co hcp K_1 and K_2 and the interface anisotropy contribution K_{S} . The angle θ_n ($n = 1, \dots, N$, N = number of Co layers) is defined by the angle between the sample normal and the magnetization \mathbf{M} . The magnetic field H is aligned perpendicular to the surface ($\theta_{\text{H}} = 0$).

Taking into account the experimental values for K_{S} and M_{S} we have calculated the magnetocrystalline anisotropy constants K_1 and K_2 by a fit to the data points shown by the solid lines in Figs. 1(a) and 1(b). Best results are obtained with the values $K_1 = 2.1 \times 10^5 \text{ J/m}^3$ and $K_2 = 1.1 \times 10^5 \text{ J/m}^3$. These data are in a good agreement with literature values⁶⁻⁸ for bulk Co.

For Co thicknesses $14 \text{ \AA} \geq t_{\text{Co}} \geq 12 \text{ \AA}$ polar MOKE hysteresis curves as displaced in Fig. 1(c) exhibit a reduced remanent magnetization which indicates that perpendicular alignment of the magnetization is not reached. The corresponding longitudinal MOKE curve in Fig. 1(g) exhibits a mixture of polar and longitudinal contributions indicating a slanted easy axis with respect to the surface normal.

For Co thicknesses $< 12 \text{ \AA}$ we observe a switching of the magnetic moments back into the in-plane orientation [Fig. 1(d)]. Direct observations of the easy axis of the superlattices were performed by a simplified torque magnetometer. The easy axis of the sample is oriented parallel to the applied

FIG. 1. MOKE hysteresis loops of Co/Cr superlattices as a function of Co layer thickness: (a)–(d) for polar configuration (out-of-plane) and (e)–(h) longitudinal (in-plane) configuration. The solid lines (a) and (b) are fits to the data points using Eq. (1).

magnetic field and the angle between the magnetic field and the sample normal corresponds to the easy axis orientation. To eliminate any influence from the torque by the attachment wire the position of the sample has to be the same with and without magnetic field. The experimental data are shown in Fig. 2. The easy axis exhibits a continuous rotation from the in-plane orientation of $\theta_M = \pi/2$ for thick Co layers to a nearly perpendicular direction ($\theta_M = 0$) with decreasing Co layer thickness at $t_{Co} = 12$ Å. For $t_{Co} < 12$ Å the magnetic anisotropy rotates back from the perpendicular to the in-plane orientation in a good agreement to our MOKE data.

A reorientation has also been observed in Cu/Ni/Cu trilayers.⁹ However, in contrast to the present work, this reorientation is related to a coherent–incoherent growth mode. Normally one would expect a complete switching of the easy axis from an in-plane to a perpendicular orientation within a thickness range of $\Delta t_{Co} \approx 2$ Å around the critical thickness. The dashed line in Fig. 2 represents the expected behavior of the easy axis according to the model as described by Eq. (1). The experimental results indicate that new anisotropy contributions have to be taken into account for small Co layer thicknesses.

We believe that the reorientation of the easy axis is strongly affected by the continuous structural phase transition of the Co layers from hcp to bcc. The experimental results can be explained by a change of the interface anisotropy from a negative value for hcp Co to a positive value for Co in the bcc structure preferring an in-plane orientation of the magnetization. The interface anisotropy of bcc Co ap-

FIG. 2. Easy axis of the magnetization as a function of the Co layer thickness. The solid line is a guide to the eye. The broken line is calculated using Eq. (1) with $H=0$. The experimental "torque" arrangement is shown in the inset. The in-plane component of the easy axis is aligned horizontally.

pears to be opposite to the hcp interface anisotropy.

The observed epitaxial strain of $e_1 = +7\%$, $e_2 = -4\%$, and $e_3 = +0.2\%$ for $t_{Co} = 10$ Å gives rise to strong magneto-elastic contributions. Model calculations according to Mason¹⁰ lead to a perpendicular magneto-elastic contribution of $K_{ME} \approx 6$ kOe. This value of K_{ME} is not big enough to overcome the in-plane contributions K_1 , K_2 , and the shape anisotropy. On the other hand, it is not small enough to be neglected in the lower Co-thickness regime.

The magnetization of the samples is not significantly reduced down to $t_{Co} = 9$ Å, indicating sharp interfaces and interdiffusion of not > 2 Å. Therefore we can exclude decreasing magnetization effects as described for Co/Pt (Ref. 4) for ultrathin Co thicknesses.

In contrast to the out-of-plane results described so far, the in-plane anisotropy of the superlattices is independent of the Co layer thickness for $t_{Co} \leq 16$ Å. Depending on the crystal domain structure¹ we observe uniaxial or fourfold in-plane magnetic anisotropies.

To study the antiferromagnetic interlayer exchange coupling, we have grown by molecular beam epitaxy (MBE) methods Co/Cr(001) superlattices with varying Cr thicknesses $t_{Cr} \approx 5$ –23 Å and with Co thicknesses of $t_{Co} \approx 10$, 12, and 22 Å. We obtain antiferromagnetic coupled superlattices with either a slanted easy axis or with an in-plane alignment of the magnetization, depending on t_{Co} . For $t_{Co} \approx 12$ Å (out-of-plane anisotropy) and a Cr thickness of 10 Å we observe antiferromagnetic hysteresis curves as shown in Fig. 3, whose shape can be explained by a spin structure as described further below. As shown in Fig. 4 the first maximum of the antiferromagnetic coupling occurs at $t_{Cr} = 6$ Å, which is in a good agreement to the results of Fe/Cr(001).¹¹ The samples are not saturated in this Cr thickness regime up to 18 kOe, implying an antiferromagnetic coupling strength of $|J_1| > 0.5$ mJ/m². Neither a second maximum nor a two monolayer oscillation of the interlayer coupling as known for the system Fe/Cr(001) (Ref. 12) has been observed so far.

For $t_{Co} = 22$ Å (in-plane anisotropy) we observe an antiferromagnetic coupling as well. The first maximum appears

FIG. 3. Experimental polar MOKE hysteresis loop and the magnetization curve according to the theory (solid line). More details are given in the text.

to occur at the same Cr thickness as in the previous case. Again neither a second maximum nor a monolayer oscillation was observed.

In order to theoretically describe the hysteresis curves and spin structures of the antiferromagnetically coupled superlattices we add to the anisotropy energy E_A in Eq. (1) the bilinear exchange coupling term J_1 and a new uniaxial anisotropy term K_u using

$$NE'_A = NE_A + \sum_{n=1}^N K_u \cos^2(\theta_n - \theta_u) - \sum_{n=1}^{N-1} \frac{1}{t_{Co}} 2J_1 \cos(\theta_n - \theta_{n-1}). \quad (2)$$

The angle θ_u defines the orientation of the easy axis with respect to the sample normal direction. The origin of the intermediate anisotropy term K_u is not quite clear at the present time, but necessary for a phenomenological description of the anisotropy and coupling behavior at Co layer thickness < 14 Å. The introduction of K_u is phenomenologically justified for the slanted easy axis. Taking into account the anisotropy constants K_1 , K_2 , and K_S and using

FIG. 4. Saturation field as a function of the Cr layer thickness. The arrows in the thickness regime of 6 Å indicate that the samples were not saturated up to 18 kOe.

FIG. 5. Spin structure as determined from absolute minima calculations using Eq. (2). To simplify the presentation, the spin orientation in the individual Co layers are plotted side by side.

$K_u = 2 \times 10^5$ J/m³ and $\theta_u = 54^\circ$ as parameters, we have performed absolute minima calculations of Eq. (2) to determine J_1 at $t_{Co} = 12.5$ Å from a fit to the MOKE hysteresis data points as shown in Fig. 3. The calculated magnetization curve in Fig. 3 (solid line) agrees very well to the data points using $J_1 = -0.31$ mJ/m².

In contrast to bilayer systems the remagnetization process of the Co/Cr(001) superlattices exhibit strong asymmetric spin structures. The rather complicated hysteresis loop in Fig. 3 can be explained as follows: In remanence the magnetic moments are oriented antiparallel along the easy axis direction [Fig. 5(a)]. A surface spin flip transition with domain wall nucleation at H_1 (Fig. 3) leads to an asymmetric spin structure [Fig. 5(b)]. At slightly higher fields H_2 we observe "domain wall" motion to a more stable state with a symmetric spin structure in respect to the center of the superlattice [Fig. 5(c)]. At higher fields ($H > H_3$) we observe a switching of the spins into the direction of the magnetic field [Fig. 5(d)]. Afterwards coherent rotation of the layer spins occurs until saturation will be achieved. The two outermost Co layers differ slightly in their orientation from the inner layers, because they are only coupled to one neighbor.

The crossed MOKE curve in Fig. 3 can be explained by the fact that the top Co layer provides a stronger contribution to the Kerr signal than the inner layers. The slight difference in the saturation regime is not yet well understood.

We would like to thank J. Podschwadek and W. Oswald for their technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft through SFB 166.

Spin-resolved density of states of 3d magnets

A. K. See and L. E. Klebanoff^{a)}

Department of Chemistry and Zettlemoyer Center for Surface Studies, Lehigh University, Bethlehem, Pennsylvania 18015

Spin-resolved x-ray photoelectron spectroscopy and high-resolution x-ray photoelectron spectroscopy studies of the valence electronic structure of ferromagnetic Fe, Co, $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$, and Ni are reported, and compared with theoretical densities of states. Agreement between theory and experiment is very good for ferromagnetic Fe and $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$. For metallic Co, experiment agrees poorly with theory incorporating a 1.5 eV exchange splitting, suggesting a reduced (1.2 eV) exchange splitting attributable to valence electron correlation in Co metal. Ferromagnetic Ni shows poor agreement between experiment and theory, particularly in the \uparrow -spin channel. © 1996 American Institute of Physics. [S0021-8979(96)16908-6]

I. INTRODUCTION

Previous x-ray photoelectron spectroscopy (XPS) studies of the valence-band density of states (DOS) of the 3d ferromagnetic metals have been spin-integrated experiments.¹ This article presents spin-resolved x-ray photoelectron spectroscopy (SRXPS) studies of the DOS of Fe, Co, a Co-based magnetic glass $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$, and Ni. Complementary spin-integrated high-energy-resolution x-ray photoelectron spectroscopy (HRXPS) spectra are also reported for these metals with a higher energy resolution than previously attained. The SRXPS and HRXPS data are compared with majority-spin (\uparrow -spin) and minority-spin (\downarrow -spin) theoretical DOS for these ferromagnetic metals, as recently calculated by Moruzzi.²

II. EXPERIMENT

The SRXPS instrumentation and measurement process has been described in detail elsewhere.³ Details of sample preparation and characterization can be found in Ref. 4. Briefly, the Fe sample was a 80-Å-thick single-crystal Fe(011) film prepared by evaporating high-purity iron onto a W(011) substrate. The cobalt-glass $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$ sample was an amorphous metallic ribbon. The Co-metal sample was a thick (in excess of 60 Å) polycrystalline film prepared by evaporation of high-purity Co onto the cobalt-based magnetic glass. The Ni sample was a Ni(011) single crystal that was cleaned by standard procedures. A Cu sample used for control SRXPS experiments was a thick polycrystalline film prepared by evaporating high-purity Cu onto the Ni(011) single crystal.

SRXPS allows the decomposition of an XPS spectrum into separate majority-spin ($N\uparrow$) and minority-spin ($N\downarrow$) contributions, respectively, in a manner described previously.³ All samples were studied in remanent saturated magnetization.

The HRXPS measurements employed a SCIENTA ESCA-300 x-ray photoelectron spectrometer, which is described in detail elsewhere.⁵ A variety of samples was used for the HRXPS studies. The Fe and Co metal samples were high-purity polycrystalline foils that were cleaned by argon-ion sputtering. The Ni sample was a Ni(011) single crystal, cleaned in the standard fashion. The amorphous metallic Co-glass sample was a sputter-cleaned thin strip of composition $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$. The sample temperature during all SRXPS and HRXPS measurements was ~ 298 K.

III. RESULTS AND DISCUSSION

SRXPS spectra for Fe, Co, the Co-glass $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$, Ni, and a Cu control sample are compared with theoretical DOS for these metals in Fig. 1. All theoretical DOS presented in this article have been calculated² using augmented spherical waves (ASW) in the "atomic sphere" and local density approximations. For comparison with photoemission spectra, the theoretical \uparrow -spin and \downarrow -spin and l -resolved DOS are adjusted with calculated atomic σ_{4s} , σ_{4p} , and σ_{3d} cross sections.⁶ The variation of the valence-band cross section with energy was accounted for using Shevchik λ_{4s} , λ_{4p} , and λ_{3d} values⁷ calculated from the theoretical l -resolved DOS for each spin. The resulting (fully corrected) l -resolved DOS are then added together, truncated with the Fermi-Dirac distribution, and convoluted with a Gaussian of appropriate width to simulate the instrumental energy resolution of SRXPS or HRXPS (1.6 eV FWHM or 0.34 eV FWHM, respectively). Cross section and Shevchik parameters used for modification of theoretical DOS are given in Ref. 4.

The comparison of theoretical DOS with SRXPS and HRXPS spectra is clearly valid for the polycrystalline samples. Previous work⁸⁻¹⁰ on phonon-assisted nondirect valence transitions, and the angular acceptances used in the SRXPS and HRXPS instrumentation, indicate that contributions from wave-vector-conserving transitions would be negligible for the Ni(011) and Fe(011) single-crystal samples.

^{a)} Author to whom correspondence should be addressed.

FIG. 1. Comparison of raw SRXPS spectra of Cu, Fe, Co, $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$, and Ni with the \uparrow -spin DOS and the \downarrow -spin DOS as calculated by Moruzzi.

FIG. 2. Comparison of raw HRXPS spectra of Fe, Co, $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$ and Ni with the \uparrow -spin DOS, the \downarrow -spin DOS, and the total (\uparrow -spin + \downarrow -spin) DOS.

Since there is no calculated DOS available for $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$, a DOS derived from Co metal was used. This somewhat crude derivation involved rigidly shifting the spin-resolved Co metal DOS towards each other to reflect a $t_{2g}(\Gamma_{25'})$ exchange splitting of 0.88 eV. This accounts for the fact that the Co atoms in the glass have a smaller magnetic moment ($1.0 \mu_B$) than the Co atoms in Co metal ($1.72 \mu_B$).¹¹ Since the flat bands near Γ contribute strongly to the DOS, the modification should provide a reasonable first-order approximation to the true DOS of $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$.

A SRXPS valence-band spectrum of nonmagnetic Cu is shown at the top of Fig. 1. The $N\uparrow$ and $N\downarrow$ spectra for a nonmagnetic sample should overlap. Thus, the Cu result serves as a control, indicating our ability to measure zero spin polarization given the limited statistical condition of the SRXPS data.

For all of the comparisons shown in Fig. 1 between SRXPS experiment and theory, one of the theoretical DOS curves is normalized to the corresponding SRXPS data at the maximum of the valence-band intensity. However, the same normalization is applied to both spin-resolved DOS, so that the relative intensities of the \uparrow -spin and \downarrow -spin DOS accurately reflect the theoretical prediction.

The $N\uparrow$ and $N\downarrow$ Fe SRXPS spectra are compared with theoretical \uparrow -spin and \downarrow -spin Fe DOS in Fig. 1. The SRXPS

spectra reveal that at low ($< \sim 2$ eV) binding energy, the Fe valence-band spectrum consists of a large \uparrow -spin component accompanied by a \downarrow -spin component shifted to slightly larger binding energy. These results are in good accord with the theory of Moruzzi (Fig. 1), and are also supported by the comparison of the Fe HRXPS spectrum with theory in Fig. 2. The main Fe HRXPS valence-band peak at 0.65 eV in Fig. 2 possesses an unresolved shoulder toward high binding energy. Comparison with theory in Fig. 2 suggests the shoulder is predominantly \downarrow spin.

The Fe SRXPS data also reveal a poorly resolved feature at ~ 3 eV in the valence-band spectrum which has a large \uparrow -spin polarization, in agreement with the theoretical \uparrow -spin Fe DOS. The $N\downarrow$ peak at 1.1 ± 0.1 eV and the poorly resolved $N\uparrow$ shoulder at 3.0 ± 0.2 eV correspond to a wave-vector-averaged exchange splitting of 1.9 ± 0.2 eV, in general agreement with theory (2.0 eV).² Spin-resolved UPS studies¹² of Fe report a $t_{2g}(\Gamma_{25'})$ exchange splitting of 2.2 eV.

The SRXPS valence-band spectrum of Co metal is shown in Fig. 1. Although the $N\downarrow$ Co SRXPS spectrum agrees well with the \downarrow -spin theoretical DOS, especially toward smaller binding energy, the width and mean energy of the $N\uparrow$ Co SRXPS spectrum is poorly accounted for the \uparrow -spin Co theoretical DOS. This is also apparent in the comparison of Co metal HRXPS with theory in Fig. 2.

We attribute the overall poor agreement between Co experiment and theory to a reduced exchange splitting for Co metal. Prior UPS studies¹³ of Co(0001) have reported a t_{2g} exchange splitting of the 3d electrons of 1.2 eV, smaller than the 1.5 eV predicted by theory.² More recently, spin-resolved UPS studies of fcc Co films grown on Cu(111) report an exchange splitting of 1.4 eV,¹⁴ although the $\Gamma_{25'}$ \uparrow -spin peak position was not obvious from the data. The HRXPS spectrum of Co metal in Fig. 2 compares more favorably to a theoretical DOS in which the \uparrow -spin and \downarrow -spin DOS have been shifted toward each other to reflect a reduced t_{2g} exchange splitting of 1.2 eV.⁴ This crude modification of the theory leads to better agreement with HRXPS experiment for the large Co peak at 0.42 eV, and better energy agreement for the hump at 1.75 eV. The relative intensities within the valence band are, however, not accurately predicted.

The SRXPS data of $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$ in Fig. 1 are in good agreement with the theoretical DOS that were "synthesized" from the Co-metal DOS. The position and relative intensities of the main $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$ $N\uparrow$ and $N\downarrow$ SRXPS peaks near ~ 1.5 eV agree well with their theoretical spin-resolved counterparts.

The agreement in Fig. 2 between the HRXPS data for $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$ and the theoretical DOS for the glass synthesized from the DOS of Co metal is better than for Co metal itself. The first peak at 0.40 eV in the HRXPS spectrum is very accurately reproduced by the theoretical DOS. The spectral hump at 1.50 eV in the HRXPS spectrum would seem to be a composite of the two DOS peaks at 1.30 and 2.11 eV in the theory. The HRXPS spectrum and theory are in good agreement regarding the relative intensity and location of this hump, suggesting that this feature is strongly determined by the reduced 3d-exchange splitting in the glass.

Interestingly, the agreement between theoretical and experimental DOS is better for $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$, for which there is increased delocalization of the Co 3d bands due to hybridization with the metalloid components,¹¹ than for Co metal. Similarly, the agreement between experimental and theoretical DOS is better for Fe, which has a more delocalized 3d band structure, than for Co metal. The agreement between experiment and theory for $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$ and Fe suggest that the poor agreement for Co metal is due to narrow-band electron correlation in Co metal that acts to reduce the effective exchange interaction and decrease the Co valence bandwidth. These correlation effects should be smaller for the more delocalized 3d bands of Fe and $\text{Co}_{66}\text{Fe}_4\text{Ni}_1\text{B}_{14}\text{Si}_{15}$. Interestingly, these correlations in Co do not lead to discrete satellite structure in valence-band or

core-level photoemission from Co metal,¹¹ as they do for Ni metal.¹⁵

Prior UPS data¹⁶ suggest that the exchange splitting in Ni is 0.31 eV, smaller than the 0.60 eV splitting predicted by band theory.² Kamper *et al.*¹⁷ using spin-resolved UPS, have shown that the Ni exchange splitting varies with e_g and t_{2g} character. The exchange splitting of e_g states is 0.16 eV, while that for t_{2g} states is 0.33 eV. The average exchange splitting is 0.24 eV. The SRXPS spectrum of Ni is shown in Fig. 1. Band theory gives a particularly bad account of the $N\uparrow$ component, in a manner consistent with a reduced exchange splitting. Previous theory¹⁵ has assigned narrow-band correlations in Ni as the cause of the reduced Ni exchange splitting. The 6 eV satellite displays strong \uparrow -spin polarization. The origin of this spin polarization has been discussed,¹⁸ and will not be considered here.

Electronic structure and exchange interactions in fcc Fe

M. van Schilfgaarde, V. P. Antropov,^{a)} and B. N. Harmon^{a)}
SRI International, 333 Ravenswood Avenue, Menlo Park, California 94025

We apply a new first principles approach for evaluating the spin dynamics for arbitrary magnetic systems. The method is implemented within the local density approximation and applied to γ -Fe, a frustrated system where we obtain new low-energy magnetic configurations. © 1996 American Institute of Physics. [S0021-8979(96)35408-X]

As is well known for magnetic systems, density functional (DF) theory has yielded theoretical results for ground-state properties in agreement with experiment.¹ Detailed calculations for excited state properties, or thermal properties are less satisfactory, although a number of conceptual models and some methods for the treatment of such properties have been available for some time. Nevertheless questions still abound concerning physical phenomena above the Curie temperature. For example, what is the nature of the short range order, or what is the temperature dependence of the local magnetic moments and band splitting? Recently, we formulated² a general method to evaluate the "slow" spin dynamics in the framework of *ab initio* DF. In this article, we present more complete results for the ground state of fcc Fe, a typical frustrated system, and obtain many new magnetic structures.

The fcc Fe and related systems (Ni-Fe, Fe-Mn) have been studied for many years³ as part of the "invar" problem. It also serves as a prototype model for a frustrated magnetic system. Earlier "static" calculations for fcc Fe^{4,5} have shown a dependence of the magnetic ordering on volume. Near the equilibrium volume fcc Fe was found to be nonmagnetic, but with increasing volume the antiferromagnetic (AFM) state first becomes stable and then spin spiral (SS) and finally ferromagnetic (FM) ordering appears.⁵ With our SD formalism we allow the spin system much more freedom to choose an equilibrium structure, and have found new and complex spin configurations with lower energies. We considered a unit cell consisting of 32 atoms with independent local moments. To calculate the electronic structure we used the linear-muffin-tin orbital method⁶ with and without spin-orbital coupling. Initially the spins were frozen in a random orientation and the self-consistent electronic structure determined. Then the MM were allowed to relax along the direction of the "forces."

It is known that the local-density approximation underestimates the lattice constants of the transition metals, especially for the 3d series. The gradient corrections dramatically reduce the error (though they tend to overestimate the MM by about 10%). Since gradient-corrected calculations are probably much better predictors of the ground state, we give results of simulations using a local density functional, and corresponding simulations for the gradient-corrected functional of Perdew and Wang.

Figure 1 shows the evolution of the spins for two differ-

ent lattice constants, $a = 3.59$ Å and $a = 3.73$ Å, as calculated within the local-density approximation using the functional of Barth and Hedin. For the $a = 3.59$ Å simulation, the energy dropped smoothly and the spins ordered into the four-atom/cell "triple-k" (3k) structure (all spins oriented along $[\pm 1 \pm 1 \pm 1]$ directions), with the MM about $1.6\mu_B$ (Fig. 1). For $a = 3.73$ Å, the evolution of the spins was more complex, relaxing into a nearly stable structure of 16 atoms/cell, and then finding a slightly more stable configuration with spins

FIG. 1. The left column shows the evolution of spins in a 32-atom cell of fcc Fe with $a = 3.59$ Å. Top: the starting random configuration; middle: after 75 steps; bottom: after 200 steps. This last configuration is close to a 3k structure, the minimum-energy structure allowed by the simulation (no SS allowed). The right column is similar, but for $a = 3.73$ Å. Spin configurations after 0, 20, 75, and 220 steps are shown, the last being close to the $\uparrow\uparrow\downarrow\downarrow$ structure.

^{a)}Ames Laboratory, Department of Physics & Astronomy, Iowa State University, Ames, IA 50011.

ordered in a $\uparrow\uparrow\downarrow\downarrow$ pattern along $[001]$ and a moment of about $2.3\mu_B$ (Fig. 1).

Subsequent static calculations for the 2k, 3k, FM, and $\uparrow\uparrow\downarrow\downarrow$ magnetic configurations, and similar configurations with a SS superimposed, showed that the energetically most favorable configuration exhibited a complex volume dependence. Considering first only cases with no SS (as no SS was accessible to the simulation), we find the system to be magnetically ordered at the theoretical equilibrium volume ($a = 3.44 \text{ \AA}$), in a 3k structure with small MM ($0.8\mu_B$). At that volume the 3k is nearly degenerate with nonmagnetic Fe, being only 0.9 meV/atom more stable. The 2k is also very close in energy, lying only 1.2 meV above the 3k. With increasing lattice constant the lowest-energy structure is overtaken by the AFM $\uparrow\uparrow\downarrow\downarrow$ $[001]$ structure for $a > 3.59 \text{ \AA}$, and is in turn overtaken by FM ordering for $a > 3.73 \text{ \AA}$. Including spin-orbit coupling increased the binding energy by approximately 5 meV/atom, but did not alter the relative energies of the various magnetic configurations.

It has been proposed⁵ that the minimum energy configuration for some range of volume of fcc Fe is an incommensurate $(0,0,q)$ SS, evolving into the FM structure for large lattice constants. Accordingly, we considered various magnetic configurations with a $(0,0,q)$ SS superimposed (without spin-orbital coupling), and indeed the 3k, 2k, and FM structures were further stabilized by an incommensurate SS with $1/q \approx 5-6a$. The equilibrium configuration is a 3k+SS at $a = 3.44 \text{ \AA}$ and $1/q \approx 6a$, the SS stabilizing the normal 3k structure by 1.8 meV; this is 2.0 meV lower than nonmagnetic Fe at its own equilibrium lattice constant (3.43 \AA). With increasing volume the optimal $1/q$ evolves slowly from $\approx 6a$ at $a = 3.44 \text{ \AA}$ to $\approx 5a$ at $a = 3.55 \text{ \AA}$ in both the 3k and 2k configurations. At $a = 3.55 \text{ \AA}$ the 2k+SS overtakes the 3k+SS. For $a > 3.61 \text{ \AA}$, $\uparrow\uparrow\downarrow\downarrow$ $[001]$ is the most stable structure; it is in turn overtaken by FM ordering for $a > 3.73 \text{ \AA}$. Remarkably, the simple $(0,0,q)$ SS is never the most stable structure, though at $a = 3.59 \text{ \AA}$ it is only 1 meV higher energy than the 2k+SS and $\uparrow\uparrow\downarrow\downarrow$ structures.

When the local functional of Vosko was used in place of the Barth-Hedin functional, essentially similar results were obtained. Corresponding calculations with the gradient-correction of Perdew and Wang shared some features in common with local-density results, namely, a very strong dependence of magnetic moment on lattice constant and the favoring of complex noncollinear orderings at small lattice constants, the $\uparrow\uparrow\downarrow\downarrow$ ordering at intermediate lattice constants, and FM ordering at large lattice constants. Apart from these general tendencies, gradient corrections dramatically change the results. Simulations with gradient corrections were prosecuted at $a = 3.57 \text{ \AA}$, $a = 3.61 \text{ \AA}$, and $a = 3.65 \text{ \AA}$. The latter two evolved to the $\uparrow\uparrow\downarrow\downarrow$ configuration, although the evolution to $\uparrow\uparrow\downarrow\downarrow$ for $a = 3.65 \text{ \AA}$ was rather tortuous, owing to the existence of other nearly degenerate orderings. The $a = 3.57 \text{ \AA}$ simulation evolved to a noncollinear eight-atom configuration shown in Fig. 2. This antiferromagnetic configuration has two inequivalent atoms (a low-spin state marked "L" and a high-spin state marked "H"), and may be viewed as a four-atom structure with a commensurate $(0,1/2,0)$ SS superimposed. For $a < 3.48 \text{ \AA}$, the angle ϕ in Fig. 2 is $\pi/2$, so that

FIG. 2. Eight-atom cell found by the simulation. "H" marks the high-spin moments; "L" marks the low-spin moments. All moments are oriented in the $x-z$ plane. For small a , H lie along the x axis. For increasing $a > 3.50 \text{ \AA}$, the H spins rotate smoothly in the $x-z$ plane, increasing to an orientation where all NN angles are approximately 0° , 60° , or 120° .

all spins are aligned at 0° , 90° , or 180° . For increasing $a > 3.48 \text{ \AA}$, ϕ smoothly decreases to a value where every angle is approximately 60° or 120° . This configuration is the most stable one we found for $a < 3.54 \text{ \AA}$ (Fig. 3). For $3.54 \text{ \AA} < a < 3.65 \text{ \AA}$, which includes the global minimum energy at $a = 3.61 \text{ \AA}$, the $\uparrow\uparrow\downarrow\downarrow$ is the most stable. For $a > 3.65 \text{ \AA}$, fcc Fe ordered ferromagnetically. Once again, the SS was never the stable structure, though it is nearly degenerate with the eight-atom configuration (Fig. 1).

The low-energy magnetic configurations are generally different stacking sequences along $[001]$ planes, with all spins lying perpendicular to the stacking. Moreover, with the

FIG. 3. Total energies as a function of a for several configurations. The global minimum-energy structure is the $\uparrow\uparrow\downarrow\downarrow$ structure. For small a , the eight-atom configuration is lowest in energy; for large a , the FM configuration is lowest. Note the two distinct energy-volume curves for the FM configuration, corresponding to a low-spin and a high-spin state.

exception of the eight-atom structures, the remaining structures had all spins within a plane and were ferromagnetically aligned. To investigate of the effective exchange coupling parameters we consider an effective planar Hamiltonian coupling neighboring planes along the [001] direction, with spins in each plane aligned ferromagnetically in the plane. The coupling may be decomposed as a Fourier series of the rotation angle $\phi_i - \phi_j$ between plane i and j . To determining the coupling parameters, we consider a cell of four independent planes. By considering a continual rotation starting from a FM (++++) configuration to the AFM (+--+), and another from the FM to the +-+- configuration, there is information to extract two parameters, namely the first- and second-neighbor couplings J^1 and J^2 . (More distant-neighbor coupling is neglected.) The effective exchange Hamiltonian may then be written

$$H_{\text{eff}} = \sum (J_k^1 \cos k\varphi_1 + J_k^2 \cos k\varphi_2). \quad (1)$$

By construction, this Hamiltonian fits the FM-AFM and FM-(+-+-) energy difference exactly. We mention in passing that the MM depends rather strongly on the configuration, so any attempt to construct it by small displacements about some starting configuration is doomed to fail. The J for the bilinear biquadratic and bicubic terms are listed in Table I. It is seen that the NN bilinear coupling rapidly evolves from nearly zero at $a = 3.59 \text{ \AA}$ to a large negative value. Near the point where it becomes comparable to the 2NN bilinear term, there is a transition from a the AFM (+--+)- configuration to the FM. The rather large (and more slowly varying) 2NN

TABLE I. Exchange parameters according to Eq. (1) (in mRy).

a (a.u.)	Bilinear		Biquadratic		Bicubic	
	J^1	J^2	a^1	J^2	J^1	J^2
3.59	-0.22	1.89	0.39	-0.49	-0.15	-0.17
3.65	-2.65	1.42	0.22	-0.58	-0.12	-0.04
3.72	-4.34	1.16	0.14	-0.60	-0.17	0.01

bilinear term accounts for configurations favoring second neighbors antiferromagnetic. When the first NN bilinear term is very small, higher-order terms such as the biquadratic become relatively important, explaining why noncollinear ordering is found there.

Neutron scattering measurements of the critical fluctuations associated with the spin-density-wave transition at the Néel temperature, $T_N \approx 312$ K, in a single- \mathbf{Q} chromium crystal are reported. Critical fluctuations are observed emanating from allowed magnetic satellite positions and from satellite positions, corresponding to *absent* magnetic domains, at which no elastic scattering occurs. The inelastic scattering from these “silent satellites” grows rapidly with increasing temperature, becoming equal to the allowed single- \mathbf{Q} satellite scattering at T_N . The line shapes of the inelastic scattering at both the allowed and silent satellites are found to be intrinsically asymmetric, reflecting the underlying nesting geometry of the Fermi surface. Energy scans at the silent satellite positions reveal a weakly temperature dependent, characteristic energy below which the observed scattering intensity falls rapidly to zero. © 1996 American Institute of Physics. [S0021-8979(96)17008-0]

Of the electrons responsible for the magnetism of the transition metals Cr, Mn, Fe, Co, and Ni, those of chromium have the most itinerant character. In contrast to local moment systems, the experimental and theoretical properties of the magnetic critical dynamics associated with this itinerancy remain poorly understood.^{1,2} In 1960, Overhauser first demonstrated that the spin-density-wave (SDW) state presents a plausible ground state of the free electron gas, and further suggested that such a state might be responsible for the magnetism observed in chromium below its Néel temperature, $T_N \approx 312$ K.³ Direct evidence of the itinerant, SDW character of the magnetism in chromium² is observed in elastic magnetic neutron scattering experiments, where allowed magnetic Bragg peaks are observed at momenta, $\mathbf{Q}_{\pm} = (1 \pm \delta, 0, 0)$, corresponding to the “nesting” of electron and hole elements of the Fermi surface as shown in the insert to Fig. 1. The magnetic excitations associated with this ordered, SDW state have an unusually steep dispersion, $v \approx 850$ meV Å,⁴ which is also consistent with an energy scale set by the Fermi energy. Near T_N , observation of the critical fluctuations which drive the transition from an orthorhombic magnetic phase to the high temperature, cubic, paramagnetic state, is complicated by the presence of three degenerate magnetic domains in the ordered state. However, by first cooling through the Néel transition with a large field applied along a $[100]$ axis, a single-domain or single- \mathbf{Q} sample can be produced which remains unaffected by the subsequent removal of the applied field for temperatures $T < T_N$.⁵ Recent high resolution neutron scattering measurements⁶ have demonstrated that the critical fluctuations associated with T_N arise at both the allowed satellite positions corresponding to the single- \mathbf{Q} state, $\mathbf{Q}_{\pm} = (1 \pm \delta, 0, 0)$, and, surprisingly, at the “silent” satellite positions, associated with the magnetic domains excluded by single- \mathbf{Q} crystal preparation; $\mathbf{Q}_{\pm}^s = (0, 1 \pm \delta, 0), (0, 0, 1 \pm \delta)$. In this article we extend these measurements to higher resolutions and smaller energy transfers. These data indicate that the inelastic line shapes associated with both the allowed and the silent satellite scattering have an intrinsic asymmetry about \mathbf{Q}_{\pm} , consistent with the q -dependence of the Fermi

surface nesting. The temperature dependence of the observed silent satellite scattering at energy transfers of $\Delta E = 0.35$ meV peaks more sharply, and at a temperature closer to T_N , than our earlier $\Delta E = 0.5$ meV data. The corresponding q -widths associated with these data also demonstrated a more marked minima at T_N than observed earlier. However, at all temperatures the data remain far from resolution limited in q . Efforts to measure the energy dependence of the silent satellite scattering at $T = 140, 230, 280$, and 300 K are also reported. These data indicate that the silent satellite scat-

FIG. 1. (Top) temperature dependence of the elastic scattering in Cr#10 at allowed, (O) and silent, (●), satellite positions. (insert) $(hk0)$ scattering plane illustrating the nesting of the electron Fermi surface octahedron at $\Gamma = (000)$ with the slightly larger hole octahedron at $H = (100)$. The shaded nesting shown corresponds to the allowed, single- \mathbf{Q} state.

tering has a characteristic energy, $E_{ss} \approx 5$ meV, that softens weakly with increasing temperature.

The high resolution measurements presented below were performed at the HFBR H-9 triple-axis spectrometer using a 60'-40'-60'-S-80'-80' collimation configuration and unpolarized neutrons with a fixed incident energy of $E_i = 4.0$ meV. The (002) reflection of pyrolytic graphite was used to monochromate and analyze the incident and scattered neutrons. Cold beryllium was used to filter higher order (λ/n) contamination from the incident beam. Additional measurements involving larger energy transfers were performed at the H-7 spectrometer using fixed final energy neutrons ($E_f = 14.7$ meV), a pyrolytic graphite filter in the scattered beam, and a 40'-40'-S-40'-40' collimation configuration. Prior to both sets of measurements, Cr#10, an irregularly shaped 25.6-g single crystal with a 0.73° mosaic, was prepared in a single domain or single- \mathbf{Q} magnetic state by cooling through the Néel transition to room temperature with a magnetic field of $|\mathbf{H}| = 20$ T applied along the $(h00)$ crystal axis. After removing the field, the samples was mounted in a closed cycle He⁴ refrigerator with the $(00l)$ axis normal to the scattering plane. Two sets of satellites are accessible in this geometry: the $(1 \pm \delta, 0, 0)$ and $(\pm \delta, 1, 0)$ satellites, corresponding to the allowed magnetic reflections of the prepared single- \mathbf{Q} state, and the $(0, 1 \pm \delta, 0)$ and $(1, \pm \delta, 0)$ "silent satellites" of the absent $\mathbf{Q}_\pm^S = (0, 1 \pm \delta, 0)$ magnetic domain (Fig. 1 insert). After cooling to a starting a temperature of $T = 100$ K, all subsequent elastic and inelastic measurements were made with monotonically increasing temperature.

The temperature dependences of the elastic peak intensities observed at equivalent allowed, $\mathbf{Q}_- = (1 - \delta, 0, 0)$ and silent, $\mathbf{Q}_-^S = (0, 1 - \delta, 0)$, satellites are shown in Fig. 1. The ratio of these intensities, or the single- \mathbf{Q} ratio, is greater than 200:1 for all temperatures below T_N , indicating that the bulk of the sample is characterized by a single magnetic do-main. The sharp fall off of the magnetization just below T_N , and the measured value of the Néel temperature, $T_N = 312.12(2)$ K, are constant with the established, weakly first-order character of the SDW transition in pure chromium.⁷

Representative longitudinal elastic scans through the allowed and silent satellite positions, at $T = 311.95$ K ($= T_N - 0.17$ K), are shown in the top panels of Fig. 2. The peak in the allowed satellite data reflects the finite-order parameter present below T_N . The observed q -width of this scattering is entirely attributable to the finite instrument resolution: $\Delta q^{\text{meas.}} = \Delta q^{\text{res.}} = 0.011 \text{ \AA}^{-1}$. The absence of elastic scattering at the silent satellite position indicates that the single- \mathbf{Q} character of the sample remains intact at temperatures approaching T_N . The lower panels of the figure show equivalent scans taken at finite energy transfer, $\Delta E = 0.35$ meV. The strong inelastic scattering visible at the silent satellite position, which is nearly comparable to the allowed satellite scattering at this temperature, demonstrates that fluctuations at the silent satellite nesting vectors play an important role in the dynamics at $T \rightarrow T_N$. This strong dynamic response in the absence of an underlying static magnetization is an intrinsic feature of the critical dynamics of chromium and cannot be attributed to any selection rules associated with the magnetic scattering measurements. In contrast to the

FIG. 2. $T = 311.95$ K ($= T_N - 0.17$ K). (Top left) allowed elastic scattering at $(1 - \delta, 0, 0)$. (Top right) elastic scattering at the silent satellite position $(0, 1 - \delta, 0)$ (bottom panels) corresponding inelastic, $\Delta E = 0.35$ meV, scans.

elastic data, the q -widths of both the allowed and silent inelastic scans are roughly twice the instrument resolution. The corrected widths reflect a real-space, dynamic correlation length on the order of a few spin-density-wave periods ($\sim 45 \times a$). Another notable feature of the both the allowed and silent inelastic data is the asymmetry of the measured scattering intensities about their respective nesting vectors. Trial fits indicate that this is not the result of resolution related contamination from the neighboring satellite positions, but is rather an inherent feature of the inelastic SDW scattering. This asymmetry is related to the slightly better nesting that occurs for small displacements of the optimal nesting vector towards, rather than away from, the commensurate position, $\tau_m = (100)$ (see Fig. 1). We note that the energy dependence of this asymmetry has not been explored, and may well complicate arguments concerning the presence or absence of a distinct, commensurate source of scattering at higher energies where poorer instrument resolutions hinder the clear separation of contributions to the observed scattering intensities.

The temperature dependences of the allowed and silent satellite scattering at $\Delta E = 0.35$ meV are presented in Fig. 3. Critical scattering is observed at both the allowed and silent satellite positions. The peak intensities at the two satellites, shown in the top panel, agree above T_N as required by the cubic symmetry of the paramagnetic state. Below T_N , fluctuations associated with the silent satellite fall off rapidly, while the corresponding allowed satellite intensities fall to the finite level maintained by the magnetic "spin-wave" excitations of the ordered single- \mathbf{Q} state. The associated momentum widths are presented in the lower panel of the figure. The temperature dependence of the allowed satellite scattering q -width is monotonic and smoothly varying through T_N . This width remains broader than the instrument resolution at all temperatures down to $T = 270$ K, where the scattering is entirely due to spin waves. The spin-wave velocity, $v \approx 850$ meV \AA , is too sharp to be responsible for the width of this scattering, which suggests that this broadening in q is due to the damped nature of these excitations. At the silent satel-

FIG. 3. (Top) temperature dependence of the peak inelastic, $\Delta E = 0.35$ meV, intensities at the allowed, (○), and silent, (●), satellite positions. (bottom) Corresponding scan widths plotted with measured and calculated instrument resolutions.

lites, the q -width of the observed scattering has a sharp minimum at $T \approx T_N$. This width is observed to broaden more rapidly with decreasing than increasing temperatures about T_N . However, in contrast to local moment systems, the width of this scattering remains anomalously narrow at temperatures far from T_N .

To investigate whether the dynamics observed at the silent satellite positions possess a characteristic frequency, energy dependent measurements were performed at $Q_- = (0, 1 - \delta, 0)$ at $T = 140, 230, 280$, and 300 K. These data, shown in Fig. 4, demonstrate a peak in the spectral density, E_{ss} , below which the observed scattering falls off rapidly. Substantial spectral weight is also observed at higher energies. At $T = 140$ K, this peak energy is $E_{ss} \approx 5$ meV. With increasing temperature, the peak becomes more pronounced while softening somewhat in energy ($E_{ss} \approx 3.8$ meV at $T = 300$ K). In addition, the spectral weight at energies above E_{ss} appears to shift down in energy as well.

The results presented in this paper demonstrate that the SDW to paramagnetic transition in single- Q chromium is driven by critical fluctuations arising at all six satellite positions about the nominal antiferromagnetic zone center: $(1, \pm \delta, 0, 0)$, $(1, \pm \delta, 0)$ and $(1, 0, \pm \delta)$. These high resolution measurements have also revealed that the line shapes associated with the dynamics at both the allowed and silent satellite positions possess an asymmetry which reflects the underlying nesting geometry of the Fermi surface. The energy dependence of the silent satellite scattering, and particularly the

characteristic "cutoff" energy, E_{ss} , introduces a new puzzle in the understanding of SDW behavior. Efforts to quantitatively study the temperature dependence of this energy and its possible relation to other characteristic parameters of chromium (i.e., δ) are currently underway. The low energy scale of E_{ss} may be a clue useful in determining the polarization of the silent satellite fluctuations as our most recent measurements have revealed that the longitudinal excitations that dominate the low temperature dynamics at energies below $\Delta E \approx 9$ meV, also play an important role at temperatures approaching T_N . A superior single- Q sample, currently in preparation, should allow a more quantitative and systematic study of the temperature, energy, and q -dependence of this novel scattering.

We wish to thank Dr. Lawrence G. Rubin of the Francis Bitter National Magnet Laboratory for his help and advice during our efforts to field-cool our crystals. Invaluable technical assistance was provided by R. Rothe, J. Biancarosa, and R. J. Liegel. Theory of non-Heisenberg exchange: Results for localized and itinerant magnets

O. N. Mryasov and A. J. Freeman

A general formulation of intersite (layer) exchange coupling in bulk (multilayer) materials is proposed based on the treatment of the spin (layer) rotation as a perturbation in terms of the force theorem and multiple scattering theory. The expansion of the intersite (layer) exchange interaction energy gives expressions for the bilinear and biquadratic exchange. For metals, the approach is illustrated by linear muffin-tin orbital calculations of exchange coupling constants in the ferromagnetic 3D-metals and the fcc phase of bulk Fe. Long range oscillations of strongly volume dependent exchange coupling in fcc Fe appears to be the origin of the spin-density-wave instability in this metastable phase. The correctness of expressions for the limit of localized magnets is demonstrated by calculations for the antiferromagnetic insulator NiO. In contrast with other theories, this method can be used for both nonmagnetic and magnetic spacers in metallic multilayers, as is illustrated by calculations of the interfacial and interlayer exchange in Fe/Mn and Co/Mn. © 1996 American Institute of Physics. [S0021-8979(96)17108-7]

While most theoretical models of order in magnetic materials are based on the Heisenberg Hamiltonian, the basis for this theory of the exchange coupling is not as definite as its wide use may suggest. There are a variety of magnets for which the Heisenberg Hamiltonian is definitely not adequate. Detailed studies of the exchange mechanisms for ions with more than one unpaired electron¹⁻³ gives an effective spin Hamiltonian

$$H_{ij}^{\text{ex}} = -J_1^{ij}(\mathbf{s}_i \cdot \mathbf{s}_j) - J_2^{ij}(\mathbf{s}_i \cdot \mathbf{s}_j)^2 - \dots \quad (1)$$

with bilinear (J_1) and biquadratic (J_2) terms.⁴ In fact, the situation is even more complicated if conduction electrons are present, in which case the effective Hamiltonian may be a rather complicated function of the spin variables, \mathbf{s}_i .^{5,6}

One of the interesting recent discoveries is that the oscillatory exchange coupling between ferromagnetic (FM) films separated by nonmagnetic or antiferromagnetic spacer layers can be quite complicated, simultaneously displaying oscillations as well as regions of 90° coupling.⁷ The energy of the exchange coupling between layers was found⁷ to be expandable as

$$E_s = C - J_1 \cos \Theta - J_2 \cos^2 \Theta, \quad (2)$$

where J_1 is considered bilinear and J_2 biquadratic exchange and Θ is the angle between sublayer magnetizations. Metallic magnets with itinerant electrons may naturally exhibit strong non-Heisenberg exchange interactions⁵ and the definition of exchange is not so obvious. However, for small variations of the spin density, the classical Heisenberg⁸ Hamiltonian may be generalized in the form

$$H_{ij}^{\text{ex}} = - \sum_n J_n^{ij} (\mathbf{e}_i \cdot \mathbf{e}_j)^n, \quad (3)$$

where \mathbf{e}_i is a unit vector in the direction of the magnetic moment on site i and the J_n^{ij} are bilinear, biquadratic, and higher order exchange coupling constants.

Thus, there is uncertainty about the applicability of a particular model used for exchange interaction in a given system. Sometimes, and even more importantly, it may not be clear how many exchange constants should be taken into account in a theoretical model of a material, because it is not known *a priori* over what range significant interactions occur. The peculiarities of the exchange coupling are controlled by details of the electronic structure, chemical bonding, and hybridization and can be treated nowadays on the basis of modern *ab initio* methods relatively accurately.

All these factors stimulated our efforts to study exchange interactions in bulk and multilayer materials using (i) the local spin density (LSD) treatment of the many-body problem and (ii) multiple scattering theory. We consider an infinitesimal angle of rotation of the magnetic moments as a perturbation in the scope of multiple-scattering theory and the force theorem⁹ and use a generalization of this approach for the non-Heisenberg form of the exchange interaction Hamiltonian [Eq. (3)]. The expressions obtained for bilinear and biquadratic exchange turn out to have a convenient and physically transparent¹⁰ form for *ab initio* calculations. Elements of this theory were presented first in Ref. 11. An important feature of this infinitesimal angle rotation approach is that it allows a unified theory to be applied, in principle, for itinerant and localized bulk and multilayered magnetic systems, even with magnetic spacers.

In this paper, we summarize some of our recent results obtained in the scope of this approach for 3D ferromagnetic metals, localized magnets like NiO, and metallic multilayers. One of the general questions addressed is whether the theory captures the peculiarities of the exchange coupling for different magnetic substances. Now, in localized magnets, biquadratic exchange is expected to be small compared with bilinear; here $J_2/J_1 \sim (t_{ij}/U)^2$, where t_{ij} are transfer integrals for insulators (~ 0.1 – 0.5 eV) and U is the on-site Coulomb correlation energy (5 – 10 eV).¹ In the case of metallic multilayers, J_2/J_1 is observed to be about 0.15 and to occur between

well-defined ferromagnetic layers. There are no measurements available for 3D metals for which exchange occurs between not so well-defined spin momenta in contrast with multilayer materials.

Further, as is known, the effective exchange interaction constants in metals control the energy of spin waves. In particular, in the long-wave limit the dispersion relation has the form

$$\omega_{\mathbf{q}} = D|\mathbf{q}|^2, \quad (4)$$

where D is the spin-wave stiffness constant which may be expressed through bilinear exchange interaction constants ($J_{ij}^{\alpha\beta}$) between sites i, j with α, β -Cartesian coordinates of the distance vector \mathbf{r}_{ij} and magnetic moment (m) as⁹

$$D = \frac{1}{m} \sum_{\alpha, \beta} \sum_j J_{ij}^{\alpha\beta} \cdot \mathbf{r}_{ij}^{\alpha} \cdot \mathbf{r}_{ij}^{\beta}. \quad (5)$$

This sum provides a natural criterion for the number of nearest shells that have to be taken into account to get a converged result for spin-wave stiffness constants.

Results of our calculations for Fe, Co, and Ni, i.e., sums of bilinear and biquadratic exchange as well as spin-wave stiffness constants, are summarized in Table I. As can be seen, this sum is converged for bcc Fe at about 16–18 neighbors, for fcc Co 10–12, and for fcc Ni about 6–8. Thus, for the ferromagnetic 3D-metals the biquadratic term is seen to be fairly large.

In addition to spin waves, the effective exchange coupling controls the energy of noncollinear configurations. As is known from band structure calculations, fcc Fe shows a tendency to form a noncollinear ground state.^{12–15} In contrast with the well-known spin-density-wave instability of Cr that is driven by Fermi surface nesting features, from an analysis of the band structure of noncollinear configurations fcc Fe is likely an example of a frustrated system.¹³ The direct proof of this suggestion may be reached on the basis of *ab initio* calculations of the exchange coupling constants. From the calculated bilinear and biquadratic terms, we determined the energy of spin spiral magnetic configurations with distribution

$$\mathbf{m}_i = m_i(\sin \Theta \cos(\phi_i), \sin \Theta \sin(\phi_i), \cos \Theta), \quad (6)$$

with $\phi_i = \mathbf{q} \cdot \mathbf{r}_i$ for $\mathbf{q} = q(0,0,1)$ and $\Theta = \pi/2$.

In Fig. 1 we show the dependence of the total energy of spin spiral configurations calculated using the Heisenberg

FIG. 1. Total energy of spin spiral noncollinear configurations ($\Theta = \pi/2$, $\mathbf{q} = q \cdot (0,0,1)$) calculated directly by the LMTO-SS method for fcc Fe at different volumes corresponding to Wigner-Seitz radii (R_{ws}) (a) 2.66, (b) 2.69, (c) 2.72, and (d) 2.78 Å.U. Solid line with filled circles are results of direct self-consistent LMTO-SS calculations and dashed lines are Heisenberg model results obtained with exchange parameters determined for five nearest shells in the FM state.

model and the LMTO-SS method.¹² Calculations were performed for different volumes since fcc Fe shows a strong and nontrivial dependence of the exchange coupling on volume.¹⁶ We found for both the high-spin and low-spin states that taking into account the biquadratic exchange determined in the ferromagnetic state does not make a qualitative difference in terms of the tendency of fcc Fe to a form noncollinear magnetic structure. However, a comparison of the Heisenberg model and self-consistent LMTO-SS calculations shows clearly that the leading contribution to the noncollinearity of fcc Fe in high-spin state is a competition of ferro- and antiferromagnetic exchanges which are strongly volume dependent. As can be seen in Fig. 1, the Heisenberg model with exchange coupling parameters determined for five nearest-neighbor shells in the ferromagnetic state fails to reproduce the spin spiral structure as being preferable in the low-spin state. This discrepancy may be explained by strong configurational dependence of the exchange parameters of the low-spin state driven by transformation to the high-spin state with the introduction of noncollinear magnetic ordering.^{12,13}

The calculation of the exchange coupling in 3D metals is probably too hard a test of the theory because of the configurational dependence. The opposite extreme case is that of localized magnetic insulators with relatively well defined spin momenta. We calculated the bilinear and biquadratic contributions to the superexchange interaction between nearest Ni atoms through oxygen in the localized magnetic insulator NiO. The exchange parameters were determined for the antiferromagnetic ground state of type AF II. As expected,²² LDA gives an underestimated gap (~ 0.65 eV) and the magnetic moment is about $1.0 \mu_B$. Results presented in Table II clearly show that the theory correctly describes the limiting

case of a localized magnetic insulator; the ratio J_2/J_1 is predicted to be about 0.05.

Magnetic multilayers are also an example of magnets where theory may work relatively well compared with bulk metallic magnets. Hence, we applied the theory for Fe/Mn and Co/Mn metallic multilayers. The following features of this type of magnets attracted our attention: (i) large biquadratic exchange; (ii) a relatively strong magnetic spacer. Calculations performed using the LMTO-ASA method for ferromagnetic alignment of Fe layers give the results summarized in Table III. As can be seen, large biquadratic exchange is likely a peculiarity of the Co/Mn superlattice, since Fe_3/Mn_5 does not show large biquadratic exchange. We found that ferromagnetic exchange of two interfacial atoms, Co-Mn, is stronger (and enhanced in comparison with bulk

Local density approximation of magnetocrystalline anisotropy: An approach for narrowband materials

R. P. Erickson

Department of Physics, Oregon State University, Corvallis, Oregon 97331-6507

We exploit the purely magnetocrystalline response associated with the Goldstone excitation of a spontaneously magnetized system in order to describe, within a local density approach, the ground state interaction between a local magnetic moment and its surroundings, whose origin is in strong short-range (on-site) electron interactions and the hybridization of localized states. The idea is to consider an applicable form for the ground state energy, and therefore the magnetic anisotropy energy, beyond the local spin density approximation, which might be inferred from existing models of narrowband materials. © 1996 American Institute of Physics. [S0021-8979(96)41708-5]

I. INTRODUCTION

An oscillating magnetic field of radio frequency is often used in conjunction with a uniform static field to probe the Goldstone mode of a spontaneously magnetically ordered sample in order to extract information about the strength and directional character of the magnetic anisotropy and the field-induced strain, or magnetostriction. The radio frequency field is tuned to resonate with the precessional frequency of the sample's average magnetization, which rotates about the direction of the uniform field. This represents a dynamical means of gleaning information about the way in which the spin angular momentum of the sample's magnetically active electrons is coupled to the crystalline environment via the electrons' orbital angular momentum. Since it costs no exchange energy to excite the Goldstone mode, this magnetocrystalline response is obtained separately from specific information about the manner in which individual electrons are correlated.

Early attempts to calculate magnetocrystalline effects were summarized by Van Vleck,¹ who pointed out the need to account for the coupling of orbital angular momenta of neighboring atoms of itinerant systems. Stimulated by this work, Brooks² utilized band theory to make order of magnitude estimates of the intrinsic anisotropy of Fe and Ni, and refinements of his study can be found in the literature.³ More recently, within a density functional approach, Daalderop and co-workers⁴ calculated the magnetic anisotropy energy (MAE) of bulk Fe, Co, and Ni. Similar calculations have been performed for YCo₅,⁵ for example.

Industrial application of rare-earth and transition-metal compounds has sustained interest in the prediction of the magnetic properties of these materials, both in the bulk and in multilayer structures. Contemporary studies of these systems have centered on first-principle calculations, using density functional theory, within the framework of the local spin density (LSD) approximation, as in Refs. 4 and 5. Within this method, difficulties can exist in calculating the magnetic moment per atom and, particularly, the MAE. For example, the easy-axis prediction for fcc Ni, in Ref. 4, differs from experiment. It has been suggested by these authors that numerical precision may be the cause of the discrepancy; Jansen⁶ has theorized that the atomic orbital energy, or orbital polarization, which is associated with Hund's rules, should be incorporated into any such calculation. More recent results for the

local magnetic moments of YCo₅ (Ref. 7) appear to support this assessment.

Present LSD approaches, like those mentioned above, intrinsically calculate single-electron Bloch states to study magnetic properties. For example, with regard to Fe, Co, and Ni, such Bloch state descriptions successfully reproduce, to a high degree of accuracy, the observed magnitude of the local moment in these metals. Ultimately, this is a testament of band theory: the *d*-like bands of Fe, Co, and Ni, and the position of the Fermi level with respect to these states, are essential to explaining the ferromagnetism in these metals. But particularly in the oxides of these metals, other Mott insulators, and rare-earth compounds, the short-range correlations of localized *d* or *f* electrons are more difficult, perhaps impossible, to address within the local density approximation, and modifications based on the Hubbard model,⁸ and the periodic Anderson model⁹ have been proposed.

The purpose of the present discussion is to consider how, if at all possible, one might incorporate the salient features of strong short-range interactions and hybridization of localized states into a local description of the ground state energy, and therefore MAE, of a narrowband material. While a discussion of anisotropy energy is perhaps a secondary consideration when addressing the basic nature of the ground state energy of these systems, it should be remembered that the effect of spin-orbit coupling is inextricably linked, via Hund's rules, to the multiplet character of the ground state itself. In fact, as outlined in Sec. II, the explicit dependence of the Hamiltonian on the spin-orbit interaction can be exploited, via magnetocrystalline response theory, to give a local description of the strongly correlated system. In Sec. III, we consider an example of how one might formulate an approximation to the ground state energy using this approach.

II. PRELIMINARY DISCUSSION

As mentioned, one way to measure magnetocrystalline properties is to cause the average magnetization $\mathbf{M}(t)$ of a sample of volume Ω to precess in an applied field. In this section, we relate the ground state energy to the equation of motion of $\mathbf{M}(t)$ —in the zero-field, time-independent (steady-state) limit—equivalent to a virtual rotation of the average magnetization \mathbf{M} . In this way, magnetic anisotropy response can be addressed specifically, and the ground state can be resolved to be in magnetic equilibrium. To maintain simplic-

ity, we consider only the response associated with intrinsic anisotropy, neglecting shape anisotropy in addition to striction effects, and we confine our discussion to the absolute zero of temperature. We assume dissipation effects to be negligible—those associated with the relativistic origin of spin-orbit coupling, which tend to cause the magnitude of \mathbf{M} to vary with its direction \hat{M} .

We adopt a nonrelativistic approach, letting the magnetic moment operator be $\mathbf{m} = -\mu_B(\mathbf{L} + 2\mathbf{S})$, where \mathbf{L} and \mathbf{S} are the total orbital and spin angular momentum of the system, respectively, and μ_B is the Bohr magneton. At the absolute zero of temperature let a ground state be $|\hat{M}\rangle$ —dependent on \hat{M} , which is aligned with the axis of quantization and referenced from the principal axes of the crystal. The true magnetic ground state corresponds to an easy-axis direction \hat{M}_0 .

The time rate of change of $\mathbf{M}(t)$ is related to the way in which the free energy per volume varies with change in \hat{M} . At zero temperature, neglecting dissipation, and in the steady state [i.e., $d\mathbf{M}(t)/dt|_0 = 0$], we have

$$\gamma^{-1} \frac{d}{dt} \mathbf{M}(t)|_0 = -\frac{1}{\Omega} \frac{\partial}{\partial \hat{M}} E_G(\hat{M})|_{\hat{M}=\hat{M}_0} = 0, \quad (1)$$

where $E_G(\hat{M})$ is a ground state energy, and $\gamma = g\mu_B/\hbar$ is a gyromagnetic ratio. The equal sign holds for all (virtual fluctuations) \hat{M} while the equivalence sign is true for $\hat{M} = \hat{M}_0$, only—precisely the zero-torque constraint satisfied by the true ground state energy.

Consider the magnetic moment $\mathbf{m}(t)$ within a volume $V \leq \Omega$. With q_N representing the $3N$ spatial degrees of freedom of an N -particle system, (i.e., $q_1 \equiv \mathbf{x}$ is the position of one particle), the local magnetization is

$$\mathbf{M}(q_1, t) = \int dq_{N-1} \langle \hat{M} | q_N \rangle \langle q_N | \mathbf{m}(t) | q_N \rangle \langle q_N | \hat{M} \rangle, \quad (2)$$

where a sum over all relevant quantum numbers is implied. As always, $\mathbf{m}(t) = \int_V d\mathbf{q}_1 \mathbf{M}(q_1, t)$, and

$$\frac{d}{dt} \mathbf{m}(t) = \int_V d\mathbf{q}_1 \frac{\partial}{\partial t} \mathbf{M}(q_1, t) \quad (3)$$

indicates how the time rate of change of $\mathbf{m}(t)$ is related to the time rate of change of $\mathbf{M}(q_1, t)$.

Now suppose $\mathbf{M}(t)$ is aligned with an easy axis, and consider the rotation of $\mathbf{M}(q_1, t) \delta V$ away from the moment distribution associated with $\mathbf{M}(t)$, where δV is an infinitesimal volume element whose location is referenced by q_1 . There must be a restoring torque that tends to reduce the spin-orbit energy of δV , bringing $\mathbf{M}(q_1, t) \delta V$ back into the original moment configuration of the easy-axis magnetization. This is not the only torque exerted, however, because the rotation of $\mathbf{M}(q_1, t) \delta V$ away from the easy-axis configuration also augments exchange energy. The tendency of exchange energy to increase must be compensated via a second restoring torque exerted on $\mathbf{M}(q_1, t) \delta V$ by the surrounding magnetic environment.

Thus, in the presence of spin-orbit coupling, the torque on $\mathbf{M}(q_1, t) \delta V$ necessarily consists of these two parts, which can be quantified by writing the Hamiltonian as

$\mathbf{H}(\hat{M}) = \mathbf{H}_0 + \mathbf{V}_{so}(\hat{M})$. Here, \mathbf{H}_0 describes the kinetic energy of N electrons and their Coulomb interactions with the ions of the lattice and with each other, while the spin-orbit term $\mathbf{V}_{so}(\hat{M})$ imposes on the total Hamiltonian, and therefore the ground state energy, a dependence on \hat{M} via the intrinsic spin. For concreteness, we assume $\mathbf{V}_{so}(\hat{M}) = \lambda \mathbf{L} \cdot \mathbf{S}(\hat{M})$.

Having separated $\mathbf{H}(\hat{M})$ into these two parts, we write the steady-state expression $\gamma^{-1} \partial \mathbf{M}(q_1, t) / \partial t|_0 = \mathbf{P}_0(\hat{M}; q_1) + \mathbf{Q}_0(\hat{M}; q_1)$, where

$$\begin{aligned} \mathbf{P}_0(\hat{M}; q_1) &= -i \int dq_{N-1} \langle \hat{M} | q_N \rangle \langle q_N | [\mathbf{S}(t), \mathbf{H}_0] | q_N \rangle \\ &\quad \times \langle q_N | \hat{M} \rangle|_0 = -\nabla_1 \cdot \vec{\mathbf{j}}_0(\hat{M}; q_1), \end{aligned} \quad (4)$$

$$\begin{aligned} \mathbf{Q}_0(\hat{M}; q_1) &= -i \int dq_{N-1} \langle \hat{M} | q_N \rangle \langle q_N | [\mathbf{S}(t), \mathbf{V}_{so}(\hat{M})] | q_N \rangle \\ &\quad \times \langle q_N | \hat{M} \rangle|_0 = -\partial \epsilon(\hat{M}; q_1) / \partial \hat{M}. \end{aligned} \quad (5)$$

Note, for example, that the intrinsic spin operator does not commute with \mathbf{H}_0 in Eq. (4) since it is a time-dependent operator, in the Heisenberg picture. However, in passing to a steady-state limit, we necessarily treat this operator as time independent. In this way, the excitation of the local magnetization that is described by Eqs. (4) and (5) is defined to be a virtual excitation. In Eq. (4), \mathbf{S} (now regarded as time independent) commutes with electrostatic contributions to \mathbf{H}_0 since these are spin independent. The commutation of \mathbf{S} with the kinetic energy operator is described by the spin-flip current density, which (with m an electron mass) is given by

$$\vec{\mathbf{j}}_0(\hat{M}; q_1) = -\frac{\hbar^2}{2im} \lim_{q'_1 \rightarrow q_1} (\nabla_1 - \nabla_1') \mathbf{S}(\hat{M}; q_1, q'_1), \quad (6)$$

$$\mathbf{S}(\hat{M}; q_1, q'_1) = \int dq_{N-1} \langle \hat{M} | q_1 q_{N-1} \rangle \mathbf{S} \langle q'_1 q_{N-1} | \hat{M} \rangle.$$

Equation (5) is expressed in terms of a derivative of the local energy density:

$$\epsilon(\hat{M}; q_1) = \int dq_{N-1} \langle \hat{M} | q_N \rangle \langle q_N | \mathbf{H}(\hat{M}) | q_N \rangle \langle q_N | \hat{M} \rangle. \quad (7)$$

This follows by differentiating Eq. (7) with respect to \hat{M} , with total electron number density held fixed,¹⁰ i.e., replacing $\mathbf{H}(\hat{M})$ by $\partial \mathbf{V}_{so}(\hat{M}) / \partial \hat{M} = -\lambda \mathbf{L} \times \mathbf{S}(\hat{M}) = i[\mathbf{S}, \mathbf{V}_{so}(\hat{M})]$.

Putting the above definitions together, the steady-state limit of $\partial \mathbf{M}(q_1, t) / \partial t$ satisfies

$$\gamma^{-1} \frac{\partial}{\partial t} \mathbf{M}(q_1, t)|_0 + \nabla_1 \cdot \vec{\mathbf{j}}_0(\hat{M}; q_1) = -\frac{\partial}{\partial \hat{M}} \epsilon(\hat{M}; q_1), \quad (8)$$

which is the analog of Eq. (1) for an infinitesimal volume element. In the presence of spin-orbit coupling, the divergence term is necessarily indicative of an anisotropic exchange interaction between the local magnetization and the surrounding magnetic environment.

III. EXAMPLE

To make a connection between the previous section and LSD, and also the motivations of Refs. 8 and 9, we consider the following scenario: Let V be the volume of a primitive cell of a perfect crystal and assume a set of magnetically active states is localized within each cell, within a volume $V_{\text{loc}} < V$, contributing a moment $\mathbf{m}_{\text{loc}}^{(i)}$ to the total moment of the i th cell. Then suppose a virtual rotation is applied to each local moment $\mathbf{m}_{\text{loc}}^{(i)}$ so that the average magnetization is made to vary as $\sum_i \mathbf{m}_{\text{loc}}^{(i)} / \Omega$, where the sum is over all unit cells. According to Eq. (1), we then have

$$\gamma^{-1} \sum_i \frac{d}{dt} \mathbf{m}_{\text{loc}}^{(i)}(t) \Big|_0 = - \frac{\partial}{\partial \hat{M}} E_G(\hat{M}). \quad (9)$$

Now let \mathbf{m} represent the total moment in some unit cell, say the i th cell. Noting that \mathbf{m} varies as $\mathbf{m}_{\text{loc}}^{(i)}$, we have $d\mathbf{m}(t)/dt \Big|_0 = d\mathbf{m}_{\text{loc}}^{(i)}(t)/dt \Big|_0$, so that upon substituting Eq. (8) into the steady-state limit of Eq. (3) and applying Gauss's Law, we obtain

$$-\gamma^{-1} \frac{d}{dt} \mathbf{m}_{\text{loc}}^{(i)}(t) \Big|_0 = \frac{\partial}{\partial \hat{M}} \int_{V_i} dq_1 \epsilon(\hat{M}; q_1) + \mathbf{j}_0^{(i)}(\hat{M}), \quad (10)$$

where $\mathbf{j}_0^{(i)}(\hat{M}) = \int_{A_i} d\mathbf{A}_i \cdot \vec{j}_0(\hat{M}; q_1)$. Here, A_i is the surface bounding the volume V_{loc} of the i th cell, with $d\mathbf{A}_i$ directed outwardly normal to A_i . Substituting Eq. (10) into Eq. (9) and integrating,

$$E_G(\hat{M}, [\rho_\sigma]) = \int_{\Omega} dq_1 \epsilon(\hat{M}, [\rho_\sigma]; q_1) + \sum_i \int_{\hat{M}_0}^{\hat{M}} \mathbf{j}_0^{(i)}(\hat{M}') \cdot d\hat{M}'. \quad (11)$$

In Eq. (11), we have inserted the functional dependence of the ground state energy on electron number density ρ_σ ($\sigma = \uparrow, \downarrow$)—if $\mathbf{j}_0^{(i)}(\hat{M}')$ is to describe purely the rotation of $\mathbf{m}_{\text{loc}}^{(i)}$ it will not vary with ρ_σ since the magnitude of $\mathbf{m}_{\text{loc}}^{(i)}$ will remain fixed. Equation (11) describes the energy of a manifold of virtually excited magnetic states. The second term on the right of Eq. (11) represents exchange energy incurred through the rotation of local moments with respect to their true ground state orientation.

We can separate $\epsilon(\hat{M}, [\rho_\sigma]; q_1)$ into a LSD part and a strong short-range interaction part, where the polarization direction of the LSD Bloch states can be taken to be along \hat{M} while that of the localized states of the i th cell is along $\hat{m}_{\text{loc}}^{(i)}$, which is most easily referenced from \hat{M} . Of course, \hat{M} itself depends on the orientations of the various local moments, and one is therefore inclined to choose an amenable ansatz for the set of orientations $\{\hat{m}_{\text{loc}}^{(i)}\}$, such as through the imposition of a supercell geometry, not unlike earlier LSD studies of antiferromagnetic Cr.¹¹

To determine the true (real ground state within a density functional context, we must vary Eq. (11), not only with respect to number density—to obtain the usual Kohn–Sham

equations, but also with respect to \hat{M} , i.e., we must impose the constraint $\partial E_G / \partial \hat{M} = 0$, setting Eq. (1) to zero. Thus, in addition to the Kohn–Sham equations, we have the local magnetic torque (energy gradient) constraints

$$\frac{\delta}{\delta \hat{m}_{\text{loc}}^{(i)}} \int_{V_i} dq_1 \epsilon(\hat{M}, [\rho_\sigma]; q_1) + \mathbf{j}_0^{(i)}(\hat{M}) = 0, \quad (12)$$

which taken together with the Kohn–Sham equations, represent an extended set of equations that must be solved self-consistently.

The spin-flip current $\mathbf{j}_0^{(i)}(\hat{M})$ of Eq. (12) assumes fully the significance of describing the interactions between the various local moments—via the hybridization between the localized states and the Bloch states of the LSD approximation. Thus, for example, if we were to imagine approximating $\epsilon(\hat{M}, [\rho_\sigma]; q_1)$ by a LDA+U scheme,⁸ the noncollinear arrangement of local moments implicit in Eq. (11) could naturally and self-consistently account for spin-flip processes, processes that are not inherent in LDA+U itself. Clearly, even a simpler approximation of $\epsilon(\hat{M}, [\rho_\sigma]; q_1)$, by standard LSD techniques alone, could incorporate spin-flip processes in this way.

The spin-flip current has been utilized in model descriptions of the Ruderman–Kittel-type interaction of magnetic multilayers, for example.¹² Specific application of Eqs. (11) and (12) within the context of a self-consistent density functional calculation is presently being studied.

Magnetic properties of melt-quenched Ni-rich amorphous and bcc Zr–Ni alloys (abstract)

László F. Kiss, Lajos K. Varga, and Imre Bakonyi

Research Institute for Solid State Physics, Hungarian Academy of Sciences, H-1525 Budapest, POB. 49, Hungary

It has been demonstrated recently¹ that the structure of melt-quenched Zr–Ni ribbons in the vicinity of 90 at. % Ni was strongly dependent on the quenching rate: at the highest quenching rate, the alloys $\text{Zr}_{10}\text{Ni}_{90}$ and $\text{Zr}_9\text{Ni}_{91}$ could be prepared with an amorphous structure whereas at lower quenching rates the $\text{Zr}_9\text{Ni}_{91}$ alloy was prepared as a solid solution of Zr in Ni with a body-centered cubic (bcc) structure. In a preliminary measurement² we have established a Curie point (T_c) of 66 K for the $\alpha\text{-Zr}_9\text{Ni}_{91}$ ribbon which was much smaller than the value $T_c=235$ K reported³ for an $\alpha\text{-Zr}_{10}\text{Ni}_{90}$ ribbon. This discrepancy has motivated us to perform the present detailed magnetization study in the temperature range 5 to 300 K. It was also of interest to compare the Curie point of the amorphous and bcc phase with the same chemical composition. The real component χ' of the AC susceptibility as well as the magnetization isotherms up to $H=18.5$ kOe have been investigated. The measurements of χ' yielded $T=41, 66,$ and 70 K for $\alpha\text{-Zr}_{10}\text{Ni}_{90}$, $\alpha\text{-Zr}_9\text{Ni}_{91}$, and bcc- $\text{Zr}_9\text{Ni}_{91}$ ribbons, respectively. The para-ferromagnetic transitions were found to be fairly sharp although in some of these samples several transitions differing by a few degrees only could be observed. In some of the samples, however, very faint magnetic transitions indicated by a small broad peak could also be detected around 250 K. This feature can be attributed to some residual phases of either an unknown Zr–Ni intermetallic compound or of Ni(Zr) solid solution precipitates. The close coincidence of this peak with the Curie temperature reported by Kaul³ suggests that his value ($T_c=235$ K) cannot be representative of the amorphous Zr–Ni matrix but it rather may originate from ferromagnetic precipitates. The magnetization isotherms for the amorphous and bcc- $\text{Zr}_9\text{Ni}_{91}$ alloy indicated the development of a significant magnetization around the T_c values deduced from χ' . The saturation magnetization at the lowest temperature amounted to about 7 emu/g in both structural modifications. This value is reasonable in view of the reduction of T_c with respect to pure fcc-Ni. The present T_c data indicate that the critical concentration for the onset of magnetic ordering in the Zr–Ni system should be slightly below 90 at. % Ni. It can be concluded from this study that the magnetic behavior of Zr–Ni alloys at about 90 at. % Ni content is characteristic for very weak itinerant ferromagnets and the results will be analyzed in this framework with the help of Arrott plots. © 1996 American Institute of Physics. Co_2ScSn crystallizes with the cubic L_{21} Heusler structure and is an itinerant ferromagnet with $T_c=238$ K. X-ray diffraction measurements show that $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ retains the L_{21} crystal structure with an essentially unchanged lattice constant for $0 \leq x \leq 0.15$. However, T_c determined from the magnetization measurements decreases monotonically with increasing Sc concentration from 238 K for $x=0$ to 40 K for $x=0.11$, and then remains at 40 K from $x=0.11$ to 0.14. The electronic specific heat coefficient γ is enhanced from 13 mJ/mole- K^2 for Co_2ScSn ($x=0$) to 30 mJ/mole- K^2 for $x=0.13$ ($\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$). In addition, the C/T versus T^2 plot shows a leveling-off behavior at low temperatures for the $x=0.13$ sample. The γ enhancement and level-off behavior observed when a system approaches a magnetic instability are discussed in terms of the self-consistent renormalization theory of spin fluctuations for weak itinerant ferromagnets and nearly magnetic systems. © 1996 American Institute of Physics. [S0021-8979(96)17208-3]

INTRODUCTION

Co_2ScSn crystallizes with the cubic L_{21} Heusler structure and is an itinerant ferromagnet with a saturation moment of $0.51 \mu_B$ per Co atom.^{1,2} We have shown² from magnetization measurements at low applied magnetic fields that the system undergoes a transition from a paramagnetic state to a helimagnetic state at $T_c=238$ K, and exhibits spin glass behavior below 100 K. The application of high magnetic fields suppresses the helimagnetic state and the spin glass behavior, and Co_2ScSn becomes a simple ferromagnet. We have also shown³ that the substitution of Ni for Co in $(\text{Co}_{1-x}\text{Ni}_x)_2\text{ScSn}$ decreases T_c linearly with increasing Ni concentration and that T_c approaches zero in the vicinity of 40% Ni substitution ($x=0.4$). The electronic specific heat coefficient γ is enhanced from 13 mJ/mole- K^2 for Co_2ScSn ($x=0$) to 58 mJ/mole- K^2 for $x=0.4$ and $x=0.5$. In addition, for the $x=0.4$ and $x=0.5$ samples the specific heat divided by temperature (C/T) vs T^2 plot shows a leveling-off behavior at low temperatures, instead of the typical straight line behavior. γ enhancements and upturn behavior in C/T have been previously observed in f -electron systems, e.g. $(\text{Ce,Gd})\text{Sn}_3$ ⁴ and $(\text{Y,U})\text{Pd}_3$,^{5,6} when these systems are close to a magnetic instability. This behavior is also consistent with the predictions of self-consistent renormalization (SCR) theory⁷ of spin fluctuations for nearly magnetic and weak itinerant magnetic systems.

Another way to drive the system towards a nonmagnetic state which does not involve the introduction of another element into the Co_2ScSn system is to depart from the 2 to 1 Co to Sc ratio, that is to make the $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ system. This system retains the L_{21} crystal structure for $x \leq 0.15$. The temperature dependence of the magnetization and specific

heat and the T_c variation for this system are presented for $0 \leq x \leq 0.15$.

EXPERIMENT

Polycrystalline $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ samples were prepared in an inert atmosphere arc furnace with appropriate care taken to compensate for the weight loss of the more volatile Sn. The samples were wrapped in Ta foils and were annealed under high vacuum at 800 °C for 8 weeks. This long period of annealing is necessary since we have shown^{2,3} that the crystal structure and physical properties of Co_2ScSn and its related systems are significantly influenced by heat treatment. Powdered x-ray diffraction and high power, high-resolution electron microscopy measurements at room temperature were used to check sample homogeneity and crystal structure. The results indicated that $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ retains the cubic L_{21} Heusler structure with an essentially unchanged lattice constant of 6.190 Å for $0 \leq x \leq 0.15$. The magnetization was measured from 1.8 to 400 K at various magnetic fields up to 5.5 T using a commercial superconducting quantum interference device (SQUID) magnetometer. The specific heat was measured from 1.2 to 25 K in zero field and applied magnetic fields up to 4 T using a semiadiabatic heat pulse method.

RESULTS AND DISCUSSION

We have shown using magnetization, electrical resistivity, and ¹¹⁹Sn Mossbauer measurements^{2,8} that the ferromagnetic transition occurs at $T_c=238$ K for Co_2ScSn . Shown in Fig. 1 curve (a) is the temperature dependence of the magnetization of Co_2ScSn measured in an applied field of 20 Oe. It can be seen that the magnetization increases rapidly below 238 K. Below T_c , down to 100 K, the magnetization is essentially unchanged. This behavior of constant magnetization can be explained in terms of the helical magnetic state,² and

^{a)}Present address: Department of Materials Science and Engineering, University of Southern California.

FIG. 1. The temperature dependence of the magnetization measured at $H=20$ Oe for (a) Co_2ScSn and (b) $\text{Co}_{1.97}\text{Sc}_{1.03}\text{Sn}$. ZFC: zero field cooled data, and FC: field cooled data.

has also been observed for other itinerant magnets, e.g., MnSi and $\text{Fe}_{1-x}\text{Co}_x\text{Si}$.⁹⁻¹¹ Below 100 K the zero field cooled (ZFC) data increases monotonically with increasing temperature, but the field cooled (FC) data do not vary with temperature. This hysteretic behavior indicates that Co_2ScSn undergoes a second transition to a spin glass like state at low temperatures, i.e., below 100 K. We have also shown² that the helical magnetic state and spin glasslike behavior are suppressed by the application of high magnetic fields, and Co_2ScSn becomes a simple ferromagnet.

We have shown³ that T_c decreases linearly with decreasing Co concentration in the $(\text{Co}_{1-x}\text{Ni}_x)_2\text{ScSn}$ system, and approaches zero in the vicinity of 40% Ni substitution for Co ($x=0.4$). We have also measured the temperature and magnetic field dependence of the magnetization for the $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ system with $0 \leq x \leq 0.15$. The magnetization measured at low applied fields for the samples with lower Co concentrations, i.e., $0 < x \leq 0.15$, shows a similar behavior to that shown in Fig. 1 curve (a). Curve (b) in Fig. 1 shows the FC and ZFC magnetization for $\text{Co}_{1.97}\text{Sc}_{1.03}\text{Sn}$ ($x=0.03$), also measured at $H=20$ Oe. It can be seen, however, that T_c and the spin glass transition for this sample occur at lower temperatures, i.e., 190 and 55 K, respectively. Again, the helical magnetic state and spin glass behavior for these samples with lower Co concentrations can be also suppressed by the application of high magnetic fields (not shown), and the samples then become simple ferromagnets.

In order to extract the ferromagnetic transition temperature T_c , we have measured M versus H for several temperatures near T_c for every sample reported here. Arrott plots (M^2 versus H/M) for $\text{Co}_{1.9}\text{Sc}_{1.1}\text{Sn}$ ($x=0.1$) at various temperatures are shown in Fig. 2. T_c is determined as the temperature for which a linearly extrapolated curve on the Arrott plot goes through the origin. We find a T_c value of 60 K from this plot for this sample. T_c determined from Arrott plots is in good agreement with T_c defined as the temperature where $|dM/dT|$ is maximum.

FIG. 2. Arrott plots (M^2 vs H/M) at $T=56, 58, 60, 62$, and 64 K for $\text{Co}_{1.9}\text{Sc}_{1.1}\text{Sn}$.

Shown in Fig. 3 is T_c versus Sc concentration ($1+x$) for the $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ system. T_c decreases monotonically with decreasing Co concentration (increasing Sc content $1+x$) from $T_c=238$ K for Co_2ScSn ($x=0$) to 40 K for $x=0.11$. It is interesting that T_c remains almost the same (40 K) for the samples with even higher Sc concentrations in the region between $(1+x)=1.11$ and 1.14 . One might argue that Co content can not be lowered below 1.89 (or that the true maximum value of $(1+x)$ is 1.11), and that is why T_c stays unchanged for $0.11 < x \leq 0.15$. For the following reasons we rule out this speculation. First, for the samples with $0.11 < x \leq 0.15$ no detectable extra phases are seen via the x-ray diffraction measurements. Second, we did not find a contribution to the magnetization from free Co metal or magnetic impurity phases. Third, we observe that the value of the mag-

FIG. 3. T_c as a function of Sc concentration ($1+x$) for the $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ system with $0 \leq x \leq 0.15$.

FIG. 4. C/T vs T^2 plot measured at applied fields $H=0$ and $H=2$ T for $\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$. The straight line indicates a linear fit to higher temperature data from $T=5$ to 10 K.

netization at low temperatures decreases monotonically as one lowers the Co content across the entire regime, including $0.11 < x \leq 0.15$.

As mentioned earlier, the variation of γ as the system approaches a magnetic instability is of primary interest. Shown in Fig. 4 is the C/T versus T^2 data measured at $H=0$ and 2 T for $\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$. For $H=0$ γ values of 33.5 and 30 mJ/mole-K^2 are obtained from C/T at $T=1.4$ K and from a linear fit of higher temperature data ($T=5-10$ K), respectively. Either of the γ values mentioned above for $\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$ is larger than that of Co_2ScSn , i.e., $\gamma=13$ mJ/mole-K^2 . This enhanced γ behavior when the system approaches a magnetic instability has been reported previously for many f - and d -electron systems. For example, γ is greatly enhanced for 10% Gd, 20% U, and 60% Co in the $(\text{Ce}_{1-x}\text{Gd}_x)\text{Sn}_3$,⁴ $(\text{Y}_{1-x}\text{U}_x)\text{Pd}_3$,^{5,6} and $(\text{Co}_{1-x}\text{Ni}_x)_2\text{ScSn}^3$ systems, respectively.

It is clear that the C/T versus T^2 plot for $\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$ shown in Fig. 4 shows a leveling-off behavior at lower temperatures. This is behavior has also been observed in the cases of heavy fermion f -electron systems,⁴⁻⁶ enhanced paramagnetic itinerant d -electron systems¹² and weakly magnetic d -electron systems.¹³ We do not believe that the leveling-off behavior seen in C/T versus T^2 for $\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$ is due to the presence of a spin glass transition for two reasons. First a plot of T_g (spin glass transition tem-

perature) versus $1+x$ (not shown here) shows that T_g goes to zero for $1+x \sim 1.07$. Second this type of C/T versus T^2 behavior is not seen for samples which have a spin glass transition namely pure Co_2ScSn and $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ with $1+x < 1.07$. The self-consistent renormalization (SCR) theory of spin fluctuations⁷ can explain the magnetic, electric, and thermodynamic properties of nearly magnetic and weakly magnetic itinerant systems. According to the prediction of the SCR theory, an additional contribution of the form $T[\ln(T/T_{sf})]$ should be added to the specific heat resulting in a leveling-off behavior in a C/T versus T^2 plot at low temperatures. Although the applied field of 2 T reduces the specific heat over the entire temperature range, it is not sufficiently strong to suppress the spin fluctuations, and thus the leveling-off behavior in $H=2$ T remains similar to that in zero field. That is, one expects that T_{sf} is considerably larger than 2 K which would correspond to the field of 2 T.

In conclusion, we have measured the magnetization and specific heat of the $\text{Co}_{2-x}\text{Sc}_{1+x}\text{Sn}$ system with $0 \leq x \leq 0.15$. T_c decreases monotonically with decreasing Co concentration from 238 K for $x=0$ to 40 K for $x=0.11$ and then remains at 40 K between $x=0.11$ and $x=0.14$. The specific heat data for $\text{Co}_{1.87}\text{Sc}_{1.13}\text{Sn}$ show that γ is enhanced to 30 mJ/mole-K^2 and the C/T versus T^2 plot exhibits a leveling-off behavior at low temperatures.

It is shown that the indirect exchange between magnetic moments distributed in a periodic array and carried out through the conduction band results from the balance of a ferromagnetic component, static effect, and an antiferromagnetic one, polarization effect. The sign of the coupling mainly depends on the density of states at the Fermi level. For filled bands only the antiferromagnetic component exists (metallic superexchange) and, in particular, only for free electrons both components exactly compensate to each other, remaining the typical Ruderman-Kittel-Kasuya-Yosida ripple due to the oscillating character of the polarization. © 1996 American Institute of Physics. [S0021-8979(96)17308-X]

I. INTRODUCTION

In spite of increasing activity in the last few years, much controversy still remains about the role of conduction electrons in promoting indirect exchange in localized arrays of magnetic moments. This concerns, as a key subject, the physics of alternating layers of magnetic and nonmagnetic materials in which many current experiments are not particularly consistent with each other and corresponding theoretical efforts are at stake.¹ Some other long standing problems, such as the indirect exchange of magnetic ions in rare earth ternary compounds,² also want a good explanation of the general trends in the polarization sign. In all these cases the so called Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction has been invoked without much detailed analysis of other contributions, that can, however, in some cases play a crucial role.³ In the present article we make a general analysis of the dominant contributions arising from conduction band indirect exchange. We show that two independent components exist and that their balance can be shown to explain the experimental data concerning the polarization sign of ferromagnetic arrays in both rare earth compounds and alternating multilayers.

II. FIRST AND SECOND ORDER SUPEREXCHANGE PERTURBATION

The model most calculations refer to⁴ consists of an array of magnetic moments, that act as a source of magnetic field and are supposed to be fixed, immersed in band of conduction electrons. The response of the electron band to the localized magnetic moments is calculated by perturbing the conduction band hamiltonian with a term of the form $\mathbf{H}' = \mu_B \sum_i \sigma_i \cdot \mathbf{H}$, where the sum in units of Bohr magneton is extended to all electron spins σ_i . This model applies to the case of multilayers composed by alternating layers of ferromagnetic and nonmagnetic metal (for example, Co/Cu), where the array consists of finite width regions (Co) of con-

stant magnetic field \mathbf{H} separated by other regions (Cu) in which the magnetic response is included in terms of a non local susceptibility χ . It does also apply to ternary compounds involving rare earths metals, in which case the array consists of the rare earth magnetic ions, the rest of the components in the material acting only as electron suppliers.

Most of the recent work has been centered in discussing the role of the nondiagonal second order perturbation terms of \mathbf{H}' , leading to polarization of the electron gas. A well known result, the so called RKKY interaction, is the appearance of decaying oscillations of the polarization gas as a function of the distance to a fixed magnetic moment. It is clear that one should add to the latter the result of the diagonal first order perturbation correction, the so called static contribution, arising from the redistribution of spins to minimize the energy of the system, a term first discussed by Fröhlich and Nabarro and later, by Zener.⁵ It was shown⁶ that for free electrons, the static contribution could be directly obtained by including the zeroth order Fourier components ($q=0$) in the second order perturbation. Since then, most authors have simply ignored the static contribution by keeping the $q=0$ term in the second order computation.

We believe that this procedure, whereas perfectly correct in the free electron approximation, may lead to error in real systems, in which band effects are relevant. Band effects have been considered previously⁷ but, mostly, in view of correcting the RKKY second order results. We argue in the following that static and polarization effects are independent (except in the very special case of free electrons) and that seldom will the static one cancel the dc value of the polarization oscillation.

III. FERRO- VERSUS ANTIFERROMAGNETIC CONTRIBUTIONS

To be precise, we discuss now the exchange interaction between two magnetic moments that are immersed in an electron background corresponding to a given band. In order

to arrive at our main conclusion we argue in successive steps. First we consider a completely filled band not overlapping with other bands. As there are not unoccupied states within a small energy range from the uppermost occupied level, there cannot be Pauli-like electron spin flip and the only result is a second-order deformation of the electron wavefunctions leading to antiferromagnetic interaction between the magnetic moments. We want to remark that the energy difference between the ferro and antiferromagnetic states due to the second order deformation, E'_{SO} , does indeed oscillate as a function of the distance between spins but that oscillation takes place around a dc value of $E'_{SO} > 0$, i.e., in spite of the oscillation, the lowest energy configuration is always antiferromagnetic. This behavior has been derived in previous works carried out for unidimensional periodic arrays of magnetic moments.^{3,8,9} We present in the Appendix a simple argument which illustrates the origin of the antiferromagnetic character of the indirect exchange due to polarization.

Now we discuss the general case of a partially filled band. For the purpose of our argument we can divide that bands in two regions: the one, far from the Fermi level, in which the spins cannot flip and that can be considered as a filled band and the other, in the neighborhood of the Fermi level, in which, in order to decrease the energy of the system, electron spins tend to jump to unoccupied states with their spins parallel to the external magnetic moments. From the first region an antiferromagnetic contribution is expected (corresponding to second order perturbation) whereas a ferromagnetic one (corresponding to first order) arises from the second. The ferromagnetic contribution, which corresponds to first order perturbation of the electron hamiltonian \mathbf{H}' is obviously very sensitive to the density of state at the Fermi level, $N(E_F)$, in much the same way as the Pauli paramagnetism is. The overall response of the system depends on a detailed balance between the above contributions, that are not related to each other. One can think in terms of the positive polarization displacing the zero level of the negative polarization oscillation. We want to remark that unless this positive displacement cancels the mean negative value of the second order oscillation the overall behavior of the system will not switch from ferro to antiferromagnetic as a function of distance between magnetic moments. The overall behavior will be conditioned by the dominating zeroth order contribution.

Two special cases are worth discussing further. First, an experimental observation: oxides having a well defined electron gap, such as nickel oxide, are well known to have an antiferromagnetic behavior based on indirect electron exchange. We can easily explain it on the grounds that these materials have completely filled bands that prevent Pauli-like spin reorientation and allow only wavefunction redistribution. That is equivalent to think of a vanishing density of states at the Fermi level. Second, a theoretical result: in a *free electron* gas the dc mean value of the second order antiferromagnetic contribution has been shown to exactly compensate the first order ferromagnetic one (see the Appendix). Only in systems whose behavior can be approximated by a free electron gas, the second order oscillation takes place around the zero dc value resulting in a global oscillation of

antiferromagnetic versus ferromagnetic behavior as a function of distance.

IV. RARE EARTH COMPOUNDS

Rare earth, R , compounds can be described as a periodic array of $R 3^+$ ions with well localized magnetic moments, $\mu_B g_J J$, immersed in a conduction band electron sea. In order to avoid both crystalline field effects or competing localized-itinerant magnetism considerations, we focus our discussion on GdM equiatomic systems, where M is a transition metal which does not contribute to the localized magnetism, as is the case for $M = \text{In, Ag, Cu, Ni, Zn, Cd, Ga, etc.}$ ² The M ions act on the conduction band by changing $N(E_F)$. Some of these compounds are ferromagnetic (RNi, RZn, RGa) while others exhibit antiferromagnetism (RCu, RIn, and RAg). The study of the corresponding diluted ternary compounds $\text{RM}_x\text{M}'_{1-x}$ shows the evolution from one behavior to another. In this sense, for the $\text{GdNi}_{1-x}\text{Cu}_x$ orthorhombic compounds¹⁰ a change from a ferromagnetic collinear structure (for $x=0$) to an antiferromagnetic one (for $x>0.5$) is observed. Similar behavior has been found for $\text{RZn}_{1-x}\text{Cu}_x$ or $\text{RZn}_{1-x}\text{Ag}_x$ cubic alloys.^{11,12} This overall behavior can be understood on the light of the considerations we have outlined in this article. Recent band calculations¹³ have shown that $N(E_F)$ is much larger for GdZn than for GdCu . This fact would support the idea that for small $N(E_F)$, as is the case for GdCu , the antiferromagnetic coupling due to electron band polarization overcomes the ferromagnetic component associated to the static effect. As Cu is partially substituted by an increasing amount of Ni , $N(E_F)$ increases resulting in a net indirect ferromagnetic coupling. It is important to notice that the influence of the interatomic distances, quite often invoked as cause of sign change for indirect exchange, can be ruled out after considering recent results in $\text{Ho}_{1-x}\text{Y}_x\text{Ni}$ series.¹⁴ These series present cell volume changes slightly larger than in $\text{GdNi}_{1-x}\text{Cu}_x$, however, all of them are ferromagnetic. In this case, in spite of the variations of distance between magnetic ions, the magnetic coupling does not exhibit sign switch because $N(E_F)$ has not been modified, as Y and Ho atoms provide the same number of electrons to the conduction band.

V. CONCLUSIONS

In a periodic array of magnetic moments described by a conduction electron exchange hamiltonian, first (static) and second order (polarization) perturbing effects do not, in general, cancel out their mean values as function of distance between the magnetic moments in the array. The overall ferromagnetic versus antiferromagnetic behavior depends, therefore, on the balancing of those effects and, particularly, on the density of states at the Fermi level. This effect is much stronger than other often considered components such as refined RKKY corrections, correlation effects, etc. A wealth of experimental data are shown to be explained on these simple grounds, particularly the ferromagnetic versus antiferromagnetic behavior of ternary compounds including rare earth ions.

APPENDIX

Let us show that the second order perturbation term leads to an antiferromagnetic coupling. For completely filled bands or orbitals the first order vanishes and therefore only a second term contribution is expected. (This is the case for superexchange in oxides). According to Ref. 4, E'_{SO} becomes

$$E'_{SO} = E_{\text{ferr}} - E_{\text{ant}} = \sum \chi_q h_q^2{}^{\text{ant}} - \sum \chi_q h_q^2{}^{\text{ferr}}, \quad (\text{A1})$$

where h_q^{ant} and h_q^{ferr} are the Fourier components of the polarizing effective field, $\mathbf{H}^{\text{ant}}(x)$ and $\mathbf{H}^{\text{ferr}}(x)$, corresponding to the antiferromagnetic and ferromagnetic configurations of the localized moment, respectively. χ_q is the q -th Fourier component of the nonlocal susceptibility $\chi(x-x')$. It can be shown with generality that E'_{SO} is positive and can be labelled as superexchange term. The basic idea is that in a filled band one half of the electrons has spin up whereas the other half has spin down. As it has been shown for periodic arrays, $m(x)$ oscillates with the same wavelength than $H(x)$ even though it presents superimposed a shorter wavelength RKKY ripple.^{3,8,9} Consider the case of a simple cubic lattice of localized moments with interatomic distance a . If the localized moments lie in a ferromagnetic configuration $m(x)$ would oscillate with wavelength a . However, for the antiferromagnetic configuration $m(x)$ should oscillate with wavelength $2a$. In general, since χ_q varies proportionally to $\sum_k \{1/(E_k - E_{k+q})\}$, it decreases with increasing q , thus $\chi(2\pi/2a) > \chi(2\pi/a)$ and thereby E'_{SO} is positive. This general trend can be understood by considering that the wave function deformation, which gives rise to $m(x)$, requires an extra second order kinetic energy to be achieved. In other words the shorter the wavelength of the magnetic configuration the higher the second order kinetic energy required to produce $m(x)$ with the same periodicity. Hence, the polarization amplitude decreases as the wavelength of $H(x)$ decreases. Therefore the magnetic energy reduction due to the spin polarization becomes more effective as larger is the $H(x)$ wavelength.

For any band the difference between the ferro and antiferromagnetic energy configurations must also include the static contribution and according to Ref. 4 becomes

$$\Delta E = E_{\text{ferr}} - E_{\text{ant}} = -\mu_B^2 N(E_F) h_0^2 + E'_{SO}. \quad (\text{A2})$$

For the particular case of a parabolic and infinitely wide band (free electrons) the positive E'_{SO} exactly counterbalances, except for the RKKY ripple, the negative $-\mu_B^2 N(E_F) h_0^2$ static term. But, for example, in a finite parabolic band filled up to the top it is verified that $\Delta E = E'_{SO} > 0$ and therefore the indirect exchange is antiferromagnetic.

FIG. 1. Free electron spin polarization. It is shown that the antiferromagnetic background due to terms $q \neq 0$ is exactly compensated by the ferromagnetic contribution coming from the term $q=0$. The source wavelength is 9.3 times the Fermi wavelength of the free electron system.

Figure 1 shows the spin polarization profile of a free electron system polarized by a periodic source as that described in the same figure. Calculation were performed by using the Fourier terms of the free electron susceptibility⁴ in the expression $m(x) = \sum \chi_q h_q \{\exp(iqx)\}$, with and without including the term $q=0$.³

Electronic and magnetic properties of the 4d itinerant ferromagnet SrRuO₃

David J. Singh

Complex Systems Theory Branch, Naval Research Laboratory, Washington, DC 20375

Density functional calculations are used to elucidate the electronic and magnetic structure of SrRuO₃. Itinerant ferromagnetic behavior is found both in the cubic perovskite and the actual orthorhombic structure. The calculated moment is 1.59 μ_B . Unusually strong hybridization is evident in both the electronic structure and magnetism. The Fermi velocities indicate significant spin differentiation of the transport properties. [S0021-8979(96)17408-6]

INTRODUCTION

Although known for some time,¹⁻⁵ there has been a recent revival of interest in the ferromagnetic (FM) perovskite, SrRuO₃.⁶⁻¹⁶ This is driven partially by technological applications for metallic perovskite substrates.^{6,7} However, SrRuO₃ also has attracted considerable interest in its own right. First of all, 4d FM is rare, occurring only in a handful of compounds and certain low-dimensional systems. Second, metallic FM perovskites are of current interest due to the discovery of colossal magnetoresistance (CMR) in (La,Ca) MnO₃. Finally, superconductivity has recently been reported in the next member ($n=1$) of the Sr_{1+n}RuO_{3+n} series,¹⁷ and this material shows interesting similarities to the high critical temperature cuprates.¹⁸⁻¹⁹

SrRuO₃ occurs in an orthorhombic, Pbnm, GdFeO₃ type structure with four formula units per cell, similar to LaMnO₃. Interestingly, SrRuO₃ also has the same nominal d electron count as LaMnO₃, although it is a FM metal rather than an antiferromagnetic (AF) insulator in its ground state. In the perovskite structure crystal field, transition metal d orbitals are split into a lower lying t_{2g} level, and a higher e_g level. These are also exchange split in magnetic perovskites. In LaMnO₃ the distortion from the cubic perovskite structure has been rationalized as due to the electron count, i.e., the remaining electron, after occupation of the majority spin t_{2g} level enters the double degenerate majority e_g orbital, leading to a Jahn-Teller (JT) instability. First principles calculations^{20,21} show that LaMnO₃ is a FM metal in the cubic perovskite structure, and takes its AF ground state when the distortion occurs. In contrast, SrRuO₃ is a FM metal, with a considerably reduced moment (relative to LaMnO₃) in its ground state. Unlike LaMnO₃ the distortion in SrRuO₃ involves mostly rotation of O octahedra, with only slight changes in the Ru-O bond lengths; this suggests different origins for the instability in the two materials. However, neither BaRuO₃ nor CaRuO₃ are known to be FM (CaRuO₃ is AFM⁴), indicating magneto-structural coupling.

Certain interesting differences are expected between 4d and 3d magnets. Generically, one expects greater itinerancy, less atomiclike character, and less important Coulomb correlation effects in 4d materials. The higher atomic numbers are expected to lead to stronger spin-orbit splittings, which will manifest themselves in stronger magneto-crystalline anisotropies. This is confirmed²² in SrRuO₃. The weak FM ($M \sim 1.5 \mu_B$) implies occupation of both minority and majority spin t_{2g} orbitals. Longo and co-workers⁴ have presented a

picture of itinerant 4d magnetism due to an instability of a 2/3 full, hybridized t_{2g} manifold.

This article elucidates the electronic and magnetic structure of SrRuO₃ using local spin density (LSD) calculations.

METHOD

Calculations were performed using a local orbital extension of the linearized augmented plane wave (LAPW) method.²³ Sphere radii of 2.05 a.u. and 1.55 a.u. were used for the cations and anions, respectively. Well converged sets of approximately 650 basis functions were used for the cubic perovskite structure, while four times this number were employed for the quadrupled orthorhombic cell. Brillouin zone averaging was done using special \mathbf{k} points. 120 \mathbf{k} points in the irreducible wedge of the zone were used for the cubic perovskite structure, while a similar mesh density, resulting in 144 \mathbf{k} points, was used for the orthorhombic structure. The orthorhombic calculations were performed for the structure of Jones *et al.*⁵ A slightly different alternate structure is given by Kobayashi *et al.*,⁸ who also studied the variation with composition. Calculations for the cubic perovskite structure were at a lattice parameter of 3.923 Å, which yields the same volume per atom.

STRUCTURE AND MAGNETISM

A FM moment of 1.17 μ_B was obtained in the cubic structure. This FM state was 40 meV lower in energy than the constrained paramagnetic solution. The wide experimental range of 1.0–1.55 μ_B has been ascribed, at least in part, to the difficulty in obtaining saturation in this material.^{9,22} Kanbayashi²² performed an extensive series of measurements on SrRuO₃ leading to the conclusion that this is due to the large magneto-crystalline anisotropy in this 4d compound. Some experimental determinations are 1.27 μ_B from the magnetization in 5.5 T at 6 K,²² 1.4 μ_B from neutron diffraction,⁴ and 1.55 μ_B from magnetization in pulsed fields.⁴ Calculations with the actual orthorhombic structure yield a FM solution of the LSDA equations, with a moment per Ru atom of 1.59 μ_B and a further energy lowering (relative to cubic FM) of 140 meV per formula unit, indicating that the energetics associated with the rotations of the oxygen octahedra are higher than the magnetic energies. Although the moment is higher than most quoted values of the experimental moment, it is quite consistent with experiment given the difficulty in saturating the material. Another impor-

FIG. 1. Band structure of cubic perovskite structure SrRuO_3 . The heavy (light) lines denote majority (minority) spin.

tant factor that could affect the moment is stoichiometry, which is a problem generic to perovskite materials, and would be anticipated to affect the moments in a (moderately) weak itinerant FM. Finally (see below), the magnetism arises from strongly hybridized itinerant Ru-O bands, leading to substantial O contributions to the moment. These will affect the fit of neutron scattering data and should be taken into account. For the actual orthorhombic structure, the moment in the Ru sphere, which approximates the $4d$ contribution, was $1.01 \mu_B$ (64%), while each O sphere contributed $0.13 \mu_B$ (total of 24%). The remaining interstitial magnetization contains both Ru $4d$ and O $2p$ contributions, although due to the small O sphere radius and the extended character of $\text{O}^{2-}p$ orbitals, the O contribution is probably dominant in this region. In any case, O contributions are large, and reflect the strongly hybridized bands near E_F .

Calculations were performed as a function of lattice parameter for the cubic perovskite structure. The moment was found to increase with increasing volume, with a slope of $0.06 \mu_B/\text{\AA}^3$ about the experimental volume. This value suggests that the moments are quite robust, although this slope should not be compared with experiment because of the assumed cubic structure. Neumeier and co-workers measured the pressure dependence of the Curie temperature, T_C finding a moderate slope, -5.7 K/GPa .⁹

ELECTRONIC PROPERTIES

The calculated band structure and projected density of states (DOS) of perovskite structure SrRuO_3 are shown in Figs. 1 and 2, respectively. The DOS for the orthorhombic structure is given in Fig. 3. These show a complex of very strongly hybridized Ru(d)-O(p) bands extending from -8 to $+4 \text{ eV}$ relative to the Fermi energy. This complex narrows to a width of less than 6 eV at the Γ point where p - d mixing is suppressed by symmetry and is broadest along the zone boundaries, consistent with a picture of strong p - d hybridization.

FIG. 2. Total and projected DOS for cubic perovskite SrRuO_3 . The projections are onto LAPW spheres and are on a per atom basis. Majority (minority) spin is shown as positive (negative). The dashed vertical line denotes E_F .

The DOS for paramagnetic SrRuO_3 (not shown) has a large peak, slightly (23 meV ; $0.2 e$ for cubic) above the Fermi level, E_F . This peak arises from flat bands near E_F . These bands originate with a pure Ru $4d e_g$ symmetry state at Γ . On each of the three orthogonal planes, $k_x=0$, $k_y=0$, and $k_z=0$ there is a band of this strong $4d$ character showing almost no dispersion in the plane, but dispersing upwards away from it due to p - d mixing. These sheets of flat bands lead to a large $N(E_F)$ (112 Ry^{-1} in the cubic structure). This

FIG. 3. DOS (per formula unit) for orthorhombic SrRuO_3 as in Fig. 2.

provides an itinerant Stoner mechanism for FM. The energy is lowered by exchange splitting this peak. The peak occurs in both structures, although it is broadened in the orthorhombic structure where there is some p component allowed in previously d -like bands. The exchange splitting (0.65 eV near E_F for the orthorhombic structure) reduces the Fermi level DOS to $N_\uparrow(E_F)=24 \text{ Ry}^{-1}$ and $N_\downarrow(E_F)=20 \text{ Ry}^{-1}$ in the cubic structure and similar values of 23 and 22 Ry^{-1} , respectively, on a per Ru basis for the orthorhombic structure.

A 0.35 eV gap is present in both spin channels above E_F for the orthorhombic structure. E_F would lie in the majority spin gap if the moment were enhanced to $2 \mu_B/\text{Ru}$, in which case half metallic behavior would be obtained. Effective half metallic FM is present in the (La,Ca)MnO₃ system, and this may be important for the CMR effect.²⁰ It is unclear what modification, if any, could enhance the moment of SrRuO₃ by $0.40 \mu_B$.

As mentioned the magnetization density has considerable $O(p)$ character reflecting the strong hybridization, which at the Fermi energy is mostly from dispersive bands like those dispersing upwards from -3 eV to cross E_F along Γ -R in the perovskite structure. Near E_F , approximately one quarter of the projection of these bands is p -like on the O spheres.

There are several sheets of Fermi surface for the cubic structure. These are flat planar sections of majority spin electrons along the $k_x=0$, $k_y=0$, and $k_z=0$ planes plus additional sections in both spins derived from dispersing p - d hybridized bands. The folding and distortion associated with the orthorhombic structure results yields quite complex Fermi surfaces with several sheets. The Fermi velocities in the orthorhombic structure are isotropic to within 10% in both spins. The average velocities, $\langle V_F \rangle_x \approx \langle V_F \rangle_y \approx \langle V_F \rangle_z$ are $0.85 \times 10^7 \text{ cm/s}$ and $1.65 \times 10^7 \text{ cm/s}$, for majority and minority spin, respectively. This implies significant spin differentiation in the transport properties, even though the $N(E_F)$ are similar (ρ often depends on $N(E_F)^{-1} \langle V_F \rangle^{-2}$ although there can be complications). If suitable chemical modifications were found to increase the exchange splitting, this differentiation would also increase becoming maximum when the half metallic state is reached and majority spin conduction is cut off.

SUMMARY

LSDA electronic structure calculations for SrRuO₃ show it to be a band FM due to a Stoner mechanism. The electronic structure shows very strong $4d$ - $2p$ hybridization through the valence band region. This reflects the extended (relative to $3d$ and $4f$ magnets) $4d$ orbitals of Ru as well as the fact that center of the $4d$ orbitals is only 1.9 eV higher

than that of the O $2p$ orbitals as measured by the band positions at Γ (there is no mixing at Γ). The largest energy scale derives from the hybridization, which sets the width of the p - d manifold (12 eV). The crystal field splittings are 3 and 2.5 eV for Ru d and O p , respectively (Γ); the exchange splittings depend on the relative p - d weights of the band, but are approximately 0.65 eV near E_F . The spin moment per Ru atom is $1.59 \mu_B$ although due to hybridization, a substantial fraction of this is O p like. Strong hybridization differentiates SrRuO₃ from most $3d$ or $4f$ magnets. This difference, the high magneto-crystalline anisotropy, the metallic conduction and the spin differentiation make SrRuO₃ a particularly interesting material for further study.

Note added in proof: P. B. Allen and co-workers have recently reported LSD calculations with similar conclusions (P.B. Allen preprint).

Magnetic and transport properties of Na doped SrRuO₃ and CaRuO₃

M. Shepard, G. Cao, S. McCall, F. Freibert, and J. E. Crow

National High Magnetic Field Laboratory, Florida State University, Tallahassee, Florida 32306

The magnetic susceptibility $\chi(T)$ ($2 \leq T \leq 400$ K) and electrical resistivity $\rho(T)$ ($2 \leq T \leq 300$ K) of undoped and Na doped SrRuO₃ and CaRuO₃ single crystals were measured. These two perovskites are orthorhombic with space group Pbnm. While both of the undoped systems exhibit metallic conductivity, SrRuO₃ is ferromagnetic with $T_c \leq 160$ K, but CaRuO₃ is paramagnetic. When a small concentration of Na ($\leq 12\%$) replaces Sr in the structure, SrRuO₃ becomes an insulator with a depressed ferromagnetic response. In contrast, Na doped CaRuO₃ ($\leq 5\%$) remains metallic with the appearance of antiferromagnetism below 70 K. The dramatic changes in magnetic and transport properties resulting from Na replacement of Sr and Ca reflects the very subtle differences driving the magnetism in SrRuO₃ and CaRuO₃. © 1996 American Institute of Physics. I. INTRODUCTION

In the past few years, there has been a renewed interest in 3d-electron transition metal perovskite and "perovskite-like" oxides. This interest has been driven by the discovery of a variety of exotic, highly correlated electron ground states, e.g., superconductivity,¹ spin-Peierls phase,² and other unusual magnetic ground states, depending on the anisotropy, the spin of the system, coupling to the lattice, and electron-spin correlations. More recently, additional interest has been stimulated by the observation of an unusually large magnetoresistance in rare-earth manganates³ which is propelled by the enormous potential of these systems in magnetic information storage and retrieval systems and in other magnetic sensors applications. However, physical properties of the 4d and 5d metal oxides, though drawing moderate attention recently, remain largely unexplored.

One class of oxides that has attracted renewed interest is strontium ruthenium oxide, SrRuO₃, and its calcium analog, calcium ruthenium oxide, CaRuO₃.⁴⁻⁶ Both of these systems have a perovskite structure and metallic-like conductivity. SrRuO₃ is a ferromagnetic metal with a Curie temperature $T_c \leq 160$ K. CaRuO₃ is also metallic, but its magnetic ground state is a little more controversial with some reports indicating a lack of long range magnetic order⁷ and others reporting suggestive evidence for an antiferromagnetic ground state with a Neel temperature $T_n \sim 110$ K.⁵ Results have been presented on the series Sr_{1-x}Ca_xRuO₃,⁸ where the system remains metallic with increasing Ca concentrations, but the ferromagnetic transition, T_c , is shifted to lower temperatures. In this article, we report results on Na doped SrRuO₃ and CaRuO₃ compounds where drastic changes in magnetic and transport properties are observed.

II. EXPERIMENTAL DETAILS AND RESULTS

The pure and doped single-crystal samples were grown in different manners. Undoped SrRuO₃ and CaRuO₃ single crystals were grown from a seeded flux mixture. First, polycrystalline samples were prepared from stoichiometric ratios of CaCO₃ or SrCO₃ and RuO₂. The ground polycrystalline SrRuO₃ (CaRuO₃) sample was then mixed with SrCl₂ (CaCl₂) in the ratio 20:1 (flux:sample).⁶ The mixture was placed into an alumina crucible, heated to 1350 K for 5 h,

cooled at a rate of 5 °C/h to 1100 °C and then rapidly cooled to room temperature. The Na doped samples were prepared by mixing stoichiometric ratios of SrCO₃ (CaCO₃) with RuO₂ in a Na-rich flux of Na₂CO₃ and the mixture was cooked using a similar temperature profile to that used for the undoped samples.

X-ray powder diffraction patterns along with SEM (scanning electron microscopy) revealed that samples were all single phase and crystal structures with lattice constants similar to those previously reported. The amount of Na in the doped crystals was determined using EDX (energy dispersive x ray). Magnetic susceptibility was measured from 1.8 K $\leq T \leq 400$ K with a magnetic field of $H \leq 7$ T using a standard commercial SQUID magnetometer. Electrical resistivity measurements from 2 K $\leq T \leq 300$ K were made using a standard four probe dc technique. Gold leads were attached to the samples with silver epoxy; the leads were baked at 300 °C for 1 h to reduce lead contact resistance.

The resistivities, $\rho(T)$, versus temperature of SrRuO₃ and Sr_{0.88}Na_{0.12}RuO₃ single crystals were measured [see Fig. 1(a)]. SrRuO₃ is a metal with resistivity values on the order of 200 $\mu\Omega$ cm, whereas (Sr,Na)RuO₃, (Na=12%) becomes insulating with a resistivity on the order of 10⁶ Ω cm. A kink in the SrRuO₃ resistivity curve in the vicinity of 130 K is indicative of the ferromagnetic transition and, thus, the reduction of spin scattering. Figure 1(b) shows a typical Fisher-Langer cusp-like anomaly that appears in the derivative of the resistivity due to changes in the short-range fluctuations of the spins near the ferromagnetic transition.⁹

Susceptibility measurements [Fig. 2(a)] give a clear indication of the presence of ferromagnetism in both systems. SrRuO₃ exhibits a ferromagnetic transition at 130 K, while Sr_{0.88}Na_{0.12}RuO₃ shows a suppressed ferromagnetic response at 70 K. Previous work on the pressure dependence of the ferromagnetic transition of SrRuO₃ shows that the transition temperature decreases as the applied pressure increases. This is similar to the response noted when systematic concentrations of the smaller divalent ion Ca replaced Sr in SrRuO₃.¹⁰ Our experimental results indicate that the addition of monovalent Na ions into SrRuO₃ also decreases the transition temperature. A fit of the paramagnetic region to the modified Curie-Weiss law, i.e., $\chi(T) = \chi_0 + C/(T + \theta)$,

FIG. 1. (a) Electrical resistivity vs temperature for SrRuO_3 and $\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$. (b) A polynomial fit of the electrical resistivity of SrRuO_3 in (a) normalized to ρ_{T_c} and the derivative of the fitted function showing a cusp-like anomaly at the ferromagnetic transition.

(shown in Fig. 3) gives values of $T_c = 126$ K and $\mu_{eff} = 2.8 \mu_B$ for SrRuO_3 and, for $\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$ $T_c = -80$ K and $\mu_{eff} = 1.9 \mu_B$. The Hund's rule value for SrRuO_3 gives $\mu_{eff} = 2.8 \mu_B$, assuming that $g = 2$. The consistency of the measured value with the Hund's rule value indicates that Ru is indeed in the low-spin state, i.e., $S = 1$.

FIG. 2. Magnetic susceptibility vs temperature for (a) SrRuO_3 and $\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$ indicating the suppression of the ferromagnetic transition response with Na doping, and for (b) CaRuO_3 and $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ showing the onset of antiferromagnetism resulting from Na doping.

FIG. 3. Inverse susceptibility vs temperature [$\Delta\chi = \chi(T) - \chi_0$] for SrRuO_3 and $\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$ above the ferromagnetic transition.

The resistivities of CaRuO_3 and $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ have been measured, although they are not shown here. CaRuO_3 is metallic, with a resistivity value similar to SrRuO_3 ($\sim 400 \mu\Omega\text{ cm}$). $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$, remains metallic with almost the same temperature dependence as that of the pure sample, but the magnitude of the resistivity has increased slightly with doping ($\sim 2 \text{ m}\Omega\text{ cm}$). No anomaly is discerned in the temperature range measured. Susceptibility measurements for CaRuO_3 and $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ are shown in Fig. 2(b). CaRuO_3 exhibits a paramagnetic response whose $1/\Delta\chi$ versus T behavior (Fig. 4) results in $\theta = T_N = 65$ and $\mu_{eff} = 1.8 \mu_B$. When Na is doped into CaRuO_3 , an apparent antiferromagnetic transition which is not present in the undoped compound appears in the vicinity of 55 K. A fit of $\chi(T)$ to the modified Curie-Weiss behavior for $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ yields $\theta = T_N = 122$ K and $\mu_{eff} = 1.0 \mu_B$.

SrRuO_3 and CaRuO_3 , systems with similar resistivities but different magnetic properties, are shown to respond quite differently to Na doping. While $\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$ remains ferromagnetic with a depressed T_c , $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ induces antiferromagnetism. The difference in the behaviors of these two doped systems can be related to the behavior of the undoped structures. SrRuO_3 and CaRuO_3 both possess col-

FIG. 4. Inverse susceptibility vs temperature ($\Delta\chi = \chi(T) - \chi_0$) for CaRuO_3 and $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ above the antiferromagnetic transition of $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$.

lective and localized $4d$ electrons. It has been suggested that the appearance of ferromagnetism in SrRuO_3 , but not CaRuO_3 , could be attributed to the greater strength of the overlap of $\text{Sr}(4d)$ - $\text{Ru}(4d)$ energy bands, compared to $\text{Ca}(4d)$ - $\text{Ru}(4d)$ overlap, and to the greater distortion from a cubic lattice in CaRuO_3 due to the difference in ionic radii.^{4,5,11} Similar behavior has been reported for $(\text{RE})\text{MnO}_3$ where an extreme sensitivity of T_c and $\rho(T, H)$ is reported for very subtle changes in the RE ionic radii.¹² This extreme sensitivity to the A - O versus B - O bond distance in ABO_3 , where B is a transition metal ion, may be a universal property of these systems.

The suppressed T_c in $\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$ indicates that the reduced size of the Na cation compared to that of Sr changes the collective-electron interactions. This behavior is similar to pressure studies, both physical and chemical substitution, which indicate that, as the cell volume is decreased, T_c is also decreased. The ferromagnetic response is sensitive to the Ru-O-Ru bond distance. CaRuO_3 was first been reported to be antiferromagnetic.⁵ Although a magnetic response might be anticipated due to the presence of ferromagnetism in SrRuO_3 , no evidence of a magnetic transition is seen for CaRuO_3 in this study, or in recent reports by other groups.⁷ However, $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ does show an antiferromagnetic response. The doping of Na into the distorted CaRuO_3 perovskite appears to change the overlap of the Ru-O-Ru bond sufficiently to lead to the support of antiferromagnetism.

In both cases, the resistivity of the doped crystal has increased from the undoped crystal. The introduction of Na ions into SrRuO_3 distorts this crystal structure and may thus localize charge carriers. The substitution of Na for Sr in SrRuO_3 leads to a reduction of μ_{eff} , $2.8 \mu_B$ (SrRuO_3) $> 1.9 \mu_B$ ($\text{Sr}_{0.88}\text{Na}_{0.12}\text{RuO}_3$), which may be an indication of a magnetic spin dilution. The resistivity of $\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$ is similar to the undoped CaRuO_3 . The effective moment μ_{eff}

of the doped crystal is less than the undoped system, $1.8 \mu_B$ (CaRuO_3) $> 1.0 \mu_B$ ($\text{Ca}_{0.95}\text{Na}_{0.05}\text{RuO}_3$), once again a possible indication of magnetic spin dilution.

The doping of Na into the well-characterized systems of SrRuO_3 and CaRuO_3 have revealed the richness of magnetic and transport properties. The most striking feature is that a small Na concentration drastically changes mechanisms of electron scattering and magnetic spin interactions for SrRuO_3 and CaRuO_3 , respectively. The difference in the sensitivity of these physical properties to the introduction of Na reflects a difference in conduction band and spin interactions between these two compounds. Further work is, therefore, necessary to fully explore the physical properties in these oxides.

Goldstone modes of incommensurate chromium alloys

R. S. Fishman

Solid State Division, P.O. Box 2008, Oak Ridge National Lab., Oak Ridge, Tennessee 37831-6032

S. H. Liu

Physics Department, University of California, San Diego, California 92093

The spin excitations about the two incommensurate wavevectors of the spin-density-wave (SDW) state in Cr are studied for the first time within the random-phase approximation. Transverse spin-wave (SW) modes and longitudinal phason modes are associated with the rotational and translational symmetries of Cr. While both mode frequencies vanish at the SDW ordering wavevectors, only the SW mode with linear dispersion and mode velocity $c = v_F/\sqrt{3}$ is undamped for nonzero frequencies. As in a local-moment system, the SW mode corresponds to the rigid rotation of the local magnetic moments. The phason modes have a nearly linear dispersion at low frequencies with velocity $c_{ph} < c$. As T approaches T_N , c_{ph} approaches c . Phason modes have been observed in the longitudinally polarized SDW state below 120 K in pure Cr and are responsible for a 60 meV peak in the cross sections midway between the satellites. © 1996 American Institute of Physics. [S0021-8979(96)17608-9]

Transition-metal antiferromagnets bare some striking similarities to their rare-earth cousins but also display some important differences. Unlike the local magnetic moments of rare earths, the spin-density wave (SDW) of transition-metal antiferromagnets consists of bound electron-hole pairs. Because the itinerant magnetic moments can fluctuate, the dynamics of transition-metal antiferromagnets are of great interest. Of the two known transition-metal antiferromagnets, only Cr alloys have been observed in an incommensurate (I) state¹ where the periodicity of the SDW is incommensurate with the lattice. Unlike the single SDW of commensurate (C) alloys with wavevector $G/2 = 2\pi/a$, the magnetization of I Cr alloys superimposes two ISDWs with wavevectors Q'_\pm on either side of $G/2$. Until recently,² very little has been known theoretically about the unique dynamics of the I phase. In this article, we present some recent results for the low-frequency Goldstone modes of I Cr alloys.

Chromium and its dilute alloys are susceptible to the formation of a SDW because of the almost perfectly nested electron a and slightly larger hole b Fermi surfaces.¹ For pure Cr, the mismatch δ of the nesting wavevectors $Q_\pm = (G/2)(1 \pm \delta)$ is about 0.036. As Cr is doped with Mn, the electron surface grows and this mismatch decreases; doping with V enlarges the hole surface and increases δ . The Coulomb attraction between electrons and holes produces a SDW consisting of electron-hole pairs in a spin-triplet state with order parameter g . In order to minimize the nesting free energy on both sides of the Fermi surfaces,³ the actual SDW wavevectors are given by $Q'_\pm = (G/2)(1 \pm \delta')$, where $0 \leq \delta' < \delta$. Doping with more than 0.2% Mn stabilizes the CSDW state with $\delta' = 0$. Pure Cr and CrV alloys are in an ISDW state with $\delta' > 0$. The three domains for the SDW wavevectors Q'_\pm correspond to the possible directions for the nesting wavevectors Q_\pm . In this article, we choose the SDW wavevectors to lie along the \hat{z} direction. Then in units of $2\pi/a$, the SDW wavevectors are $(0, 0, 1 \pm \delta')$.

Because the two ISDW wavevectors are distinct, I Cr alloys have two condensates of electron-hole pairs: the $ab \pm$ condensates contain electrons with wavevector \mathbf{k} and holes

with wavevector $Q'_\pm - \mathbf{k}$. Since each $ab \pm$ electron-hole pair carries net momentum Q'_\pm , the condensate must consist of an equal number of $ab +$ and $ab -$ pairs with total momentum equal to a multiple of $Q'_+ + Q'_- = G\hat{z}$. Correspondingly, the magnetization must sum the ISDWs at Q'_+ and Q'_- with equal weights.

The spin associated with each ISDW at site \mathbf{R} is

$$\mathbf{S}_\pm(\mathbf{R}) = \hat{m} \alpha_s g \exp\{i(Q'_\pm \cdot \mathbf{R} + \theta_\pm)\}, \quad (1)$$

where the phase constants θ_\pm may be different for the two ISDWs and α_s is a constant. Of course, the total spin is given by $\mathbf{S}(\mathbf{R}) = \mathbf{S}_+(\mathbf{R}) + \mathbf{S}_-(\mathbf{R})$. The low-frequency Goldstone modes of I Cr alloys are associated with the invariance of the free energy under translations and rotations of the ISDW state in Eq. (1). While transverse spin-wave (SW) modes are associated with the free energy's rotational invariance, longitudinal phason modes are associated with its translational invariance. Both the SW and phason modes evolve from the SDW ordering wavevectors Q'_\pm .

We recently studied² the excitations about the ISDW states within the random-phase approximation (RPA). Although the RPA is the simplest formalism to study the spin dynamics of a conventional antiferromagnet, applying the RPA to an itinerant antiferromagnet was a challenging task. Unlike the spin dynamics of a local-moment system, the spin dynamics of an itinerant antiferromagnet are driven by quasiparticle transitions. Because the nesting on one side of the Fermi surface is affected by the mismatch on the other side, a three-band model is required for the quasiparticle energies. In contrast to the simpler two-band model developed by Fedders and Martin,⁴ the three-band model introduced by Young and Sokoloff⁵ allows quasiparticle transitions between the $ab +$ and $ab -$ condensates.

Since I Cr has two ordering wavevectors, its spin susceptibility contains two sets of contributions centered around each wavevector:

$$\chi_I(\mathbf{q}, \omega) = 2(\chi_-(\mathbf{q} - \mathbf{w}, \omega) + \chi_-(-\mathbf{q} - \mathbf{w}, \omega)), \quad (2)$$

$$\chi_I(\mathbf{q}, \omega) = \chi_+(\mathbf{q} - \mathbf{w}, \omega) + \chi_+(-\mathbf{q} - \mathbf{w}, \omega), \quad (3)$$

$$\chi_{\pm}(\mathbf{q}, \omega) = -\frac{2}{V} + \frac{1}{t_{1\pm}(\mathbf{q}, \omega) + it_{2\pm}(\mathbf{q}, \omega)}, \quad (4)$$

where $\mathbf{w} = (2\pi\partial'/a)\hat{z}$ and $V > 0$ is the attractive Coulomb interaction between the electrons and holes. In Eqs. (2) and (3), the wavevector \mathbf{q} is measured from $(G/2)\hat{z}$. Hence, the crystal momentum \mathbf{p} associated with fluctuations of wavevector \mathbf{q} is $\mathbf{p} = \mathbf{q} + (G/2)\hat{z}$. For simplicity, we only consider spin fluctuations with \mathbf{q} along the \hat{z} direction. In Eq. (4), $t_{1\pm}$ and $t_{2\pm}$ are real functions of \mathbf{q} and ω whose lengthy expressions are given elsewhere.² For this discussion, we shall be primarily concerned with their analytic properties. The transverse and longitudinal cross sections are proportional to the imaginary parts of $\chi_t(\mathbf{q}, \omega)$ and $\chi_l(\mathbf{q}, \omega)$.

While the first terms in Eqs. (2) and (3) produce the satellite at \mathbf{Q}'_{+} , the reflected terms with $\mathbf{q} \rightarrow -\mathbf{q}$ produce the satellite at \mathbf{Q}'_{-} . Above the Néel temperature, $t_{1+} = t_{1-}$ and $t_{2+} = t_{2-}$. Consequently, $\chi_t = 2\chi_l$ and the spin fluctuations are isotropic. Below the Néel temperature, the collective modes are given by the zeroes of the denominator $t_{1\pm} + it_{2\pm}$. By summing the contributions from each SDW, Eqs. (2) and (3) distinguish the collective modes about one SDW from the collective modes about the other. Hence, the collective modes about \mathbf{Q}'_{\pm} are not affected by the spin excitations about \mathbf{Q}'_{\mp} .

Nonetheless, the dynamics of the two SDWs are *not* independent. To preserve the total momentum of the condensate, excitations must maintain the same number of $ab+$ and $ab-$ pairs. So a fluctuation which transfers a hole from the $ab+$ to the $ab-$ condensates is prohibited. But a fluctuation which transforms an $ab+$ pair into an $ab-$ pair and then back to an $ab+$ pair with no net change in momentum is allowed. Processes such as this one, which are absent in the two-band model, dynamically couple the two ISDWs.

A rich spectrum of collective excitations is produced by the complex quasiparticle energies of I Cr alloys. In this article, we concentrate on the Goldstone modes which evolve from the SDW wavevectors. At zero frequency, both the longitudinal and transverse susceptibilities have poles at \mathbf{Q}'_{\pm} with $t_{1\pm}(0,0) = t_{2\pm}(0,0) = 0$. At nonzero frequencies, these poles develop into the transverse SW modes and the longitudinal phason modes. Other modes associated with the oscillation of the SDW amplitude $\alpha_{s,g}$ in Eq. (1) are discussed in a more lengthy treatment.²

The transverse SW modes have linear dispersion $\omega = c|q \pm w|$ with the same mode velocity $c = v_F/\sqrt{3} \approx 1500$ meV Å as in the C regime.⁶ Due to the large size of this mode velocity, the splitting of each satellite into sidepeaks is difficult to observe experimentally. Measurements in the C phase,^{7,8} however, indicate that the SW velocity is about 30% smaller than predicted. But as discussed in Ref. 2, the effective SW velocity may be shifted by the background of incoherent excitations.

Because the magnetic moments of an itinerant system are not fixed by any conservation law, there has been some question⁹ whether the SWs in Cr alloys are similar to those in a local-moment system. We find that the two SWs with frequency ω and crystal momentum $p = \pm Q'_{\gamma} + \omega/c$ ($\gamma = \pm$)

FIG. 1. The phason mode velocity c_{ph} normalized by the SW velocity versus T/T_N for $z_0/T_N^* = 4.7$ (solid) or 7.0 (dashed).

have poles of equal strength. This suggests that the spin deviation at site \mathbf{R} should be written

$$\delta S(\mathbf{R}, t) \propto S_{\gamma}(\mathbf{R}) \exp[i(\mathbf{p} \mp \mathbf{Q}'_{\gamma}) \cdot \mathbf{R} - i\omega t], \quad (5)$$

which corresponds to the rigid rotation of each spin just as in a rare-earth antiferromagnet. In an itinerant antiferromagnet, the nodes of each static SDW with $S_{\gamma}(\mathbf{R}) = 0$ are not affected by the propagating SWs.

Phason modes are produced by the dynamics of the phases $\theta_{\pm}(\mathbf{R}, t)$ in Eq. (1). Supposing θ_0 to be the equilibrium phase and setting $\delta\theta(\mathbf{R}, t) = \theta_{\pm}(\mathbf{R}, t) - \theta_0$, the change in spin is given by

$$\delta \mathbf{S}_{\pm}(\mathbf{R}, t) = \hat{m} i \alpha_{s,g} \delta\theta(\mathbf{R}, t) \exp[i(\mathbf{Q}'_{\pm} \cdot \mathbf{R} + \theta_0)], \quad (6)$$

which is parallel to the spin polarization direction \hat{m} . Hence, phasons are longitudinal excitations which evolve from the ISDW wavevectors at \mathbf{Q}'_{\pm} . Because the CSDW state is not translationally invariant (shifting the phase changes the magnitude of the spin at every site), phason modes do not appear⁶ in the C phase of Cr alloys.

Since the zero-frequency pole in the longitudinal susceptibility is damped at any nonzero frequency, the dispersion of the phason modes is determined by the condition $t_{1+}(\mathbf{q}, \omega) = 0$ but $t_{2+}(\mathbf{q}, \omega) < 0$. For small frequencies, the phasons evolve linearly with mode velocity $c_{ph} < c$. As shown in Fig. 1, the phason mode velocity approaches the SW velocity as $T \rightarrow T_N$. The phason velocity is also an increasing function of the incommensurability energy $z_0 = 4\pi\partial v_F/\sqrt{3}a$, which grows linearly with the V concentration in CrV alloys. In the $z_0 \rightarrow \infty$ limit, our results agree with Psaltakis,¹⁰ who found that $c_{ph} = c$ for a one-dimensional ISDW with $\mathbf{Q}'_{\pm} = \mathbf{Q}_{\pm}$.

In Fig. 2, we graph the SW and phason modes evolving from the two ISDW satellites. The energy scale $T_N^* \approx 80$ meV is the Néel temperature of perfectly nested Cr with $\partial = 0$. The two satellites lie at $cq = \pm cw \approx \pm 1.903 T_N^*$. As shown, the phason modes evolve linearly up to a frequency of about $0.4 T_N^* \approx 32$ meV. Above $0.75 T_N^* \approx 60$ meV, the phason modes are overdamped and disappear. At this frequency, the inner

FIG. 2. The normalized frequency ω/T_N^* vs wavevector cq/T_N^* for the transverse SW (solid) and longitudinal phason (dashed) modes with $z_0/T_N^* = 4.7$ and $T/T_N = 0.5$.

phasons smoothly join another damped longitudinal excitation discussed in Ref. (2). The intersection of the inner phason modes with $q=0$ was recently observed by Fukuda *et al.*¹¹ as a 60 meV peak in the $G/2$ cross section. The inner phasons also bend the SW cones towards $G/2$, as first observed by Fincher *et al.*¹²

Because they evolve from the satellite wavevectors and have velocities of order v_F , phason modes have often been mistaken for SWs. In the longitudinally polarized (L) SDW state below 120 K for pure Cr, the pinning energies¹³ constrain the spin fluctuations parallel to \hat{m} and \mathbf{Q}'_{\pm} . So the low-frequency, longitudinal excitations observed by Burke *et al.*¹³ were actually phason modes.

Since the incoherent background of quasiparticle excitations is suppressed at low temperatures, experiments in the LSDW state may be able to observe the temperature dependence of the phason mode velocity. The dependence of c_{ph} on V doping may also be observable: as the phason velocity increases, the 60 meV peak in the $G/2$ cross section will move to higher energies.

Coercivity optimization studies were done on melt-spun nanocomposite $\text{Nd}_4\text{R}_2\text{Fe}_{87-x}\text{NbT}_x\text{B}_6$ ($\text{R}=\text{Nd}, \text{Y}, \text{Dy}$; $\text{T}=\text{Ag}, \text{Cu}$) isotropic ribbon samples. The maximum attainable coercivities, after adjusting the annealing time, were found to be very sensitive to the annealing temperatures. The optimum magnetic properties [$H_C=3.9$ kOe, $(\text{BH})_{\text{max}}=10$ MGOe] were obtained by annealing at 750–775 °C for a few minutes. Optimization by flash annealing gave similar results. Microstructural studies show that the grain size is greater than the theoretically predicted grain size for optimum coupling between the hard and the soft phase. With the annealing conditions used, $\text{Nd}_4\text{Dy}_2\text{Fe}_{87}\text{NbB}_6$ samples gave moderate coercivities and in $\text{Nd}_4\text{Y}_2\text{Fe}_{87}\text{NbB}_6$ samples the coercivity was reduced more than the expected reduction in the anisotropy field due to the presence of Y. © 1996 American Institute of Physics. [S0021-8979(96)37708-2]

INTRODUCTION

Nanocomposite magnets consisting of a fine mixture of magnetically soft and hard phases can lead to large reduced remanences (M_r/M_s), relatively high coercivities, and high energy products due to the exchange coupling between the hard and soft phases.^{1–3} Our previous studies in Nd–Fe–B ribbons showed a reduced remanence of 0.78 and a coercivity of 2.7 kOe resulting in an energy product of 14.45 MGOe.⁴ However microstructural studies in these samples show that the grain size is larger than the optimum size predicted by theoretical calculations^{1–3} to be of the order of the domain wall width of the hard phase (~ 10 nm).

In this article we present data on optimization studies of $\text{Nd}_4\text{R}_2\text{Fe}_{87-x}\text{NbT}_x\text{B}_6$ ($\text{R}=\text{Nd}, \text{Y}, \text{Dy}$; $\text{T}=\text{Ag}, \text{Cu}$) isotropic ribbon samples. To increase the coercivity Nb and other elements (Ag, Cu) are introduced in order to prevent grain growth and help achieve small grain sizes. Substitution of Nd with other rare earth elements influences the magnetic properties in two ways: it changes the anisotropy of the hard phase which is supposed to affect the optimum grain size and therefore the maximum coercivity and also raises the crystallization temperature of the amorphous alloy.⁵

EXPERIMENT

$\text{Nd}_4\text{R}_2\text{Fe}_{87-x}\text{NbT}_x\text{B}_6$ ingots were prepared by arc-melting the constituent elements in an argon atmosphere. Pieces of these ingots were melt-spun from a quartz tube having an orifice diameter ~ 1 mm at high wheel speeds (60 m/s). These overquenched ribbon samples were then annealed at different times and temperatures to optimize the magnetic properties. After annealing, the samples were quenched in liquid nitrogen. Some of these samples were also flash annealed in high vacuum at currents of 0.2–1 A for time intervals 5–240 s. The properties of the annealed rib-

bons are very sensitive to the current. After finding a suitable annealing current, more fine optimization could be achieved by varying the annealing time. Hysteresis loops were measured in a vibrating sample magnetometer (VSM) with a maximum field of 20 kOe. The field was applied in the plane of the ribbons and along the ribbon axis to minimize demagnetizing effects. Transmission electron microscopy (TEM) studies were carried out using a Jeol JEM-2000FX microscope.

RESULTS

The magnetic properties were optimized by annealing for various time intervals at various temperatures. The effects of the annealing conditions to the magnetic properties are shown in Figs. 1–3 for $\text{Nd}_6\text{Fe}_{87}\text{NbB}_6$, $\text{Nd}_6\text{Fe}_{86.9}\text{Ag}_{0.1}\text{NbB}_6$, and $\text{Nd}_6\text{Fe}_{86.9}\text{Cu}_{0.1}\text{NbB}_6$ ribbon samples, respectively. When annealed at 650 °C the magnetic properties are far from op-

FIG. 1. Coercivity as a function of annealing time at various annealing temperatures for a $\text{Nd}_6\text{Fe}_{86.9}\text{NbB}_6$ sample.

FIG. 2. Coercivity as a function of annealing time at various annealing temperatures for a $\text{Nd}_6\text{Fe}_{86.9}\text{Ag}_{0.1}\text{NbB}_6$ sample.

tium; at this temperature the crystallization does not lead to the formation of the 2:14:1 phase. At 700 °C the optimum coercivity (~ 3.5 kOe) is reached after 1–2 h of annealing for all the samples. At temperatures 750–775 °C the optimum annealing time is reduced to few minutes and coercivities ~ 3.9 kOe are obtained. These differences in coercivities can be attributed to the different dependence of the nucleation and growth rates on the annealing temperature⁶ resulting in different kinds of microstructure. For even higher temperatures the optimum annealing time would probably be < 1 min. For this reason flash annealing was done in one of the samples. The optimum annealing time found is of the order of only 15–20 s (Fig. 4) and the optimum value of coercivity is slightly higher than that obtained by conventional annealing on the same sample.

The grain size of these optimized $\text{Nd}_6\text{Fe}_{86.9}\text{Ag}_{0.1}\text{NbB}_6$ ribbons was of the order of 30–50 nm which is greater than the size predicted by theory for optimum exchange coupling (Fig. 5). The critical dimension of the soft phase below which the soft and hard phases are optimally coupled is predicted by theory to be of the order of the Bloch wall width of the hard phase δ given by

$$\delta = \pi(A/K)^{1/2},$$

FIG. 3. Coercivity as a function of annealing time at various annealing temperatures for a $\text{Nd}_6\text{Fe}_{86.9}\text{Cu}_{0.1}\text{NbB}_6$ sample.

FIG. 4. Coercivity as a function of annealing time for flash annealed ribbons. (a) $\text{Nd}_6\text{Fe}_{86.9}\text{Ag}_{0.1}\text{NbB}_6$ at a current of 0.75 A. (b) $\text{Nd}_4\text{Dy}_2\text{Fe}_{87}\text{NbB}_6$ at a current of 0.45 A. (c) $\text{Nd}_4\text{Y}_2\text{Fe}_{87}\text{NbB}_6$ at a current of 0.60 A.

where A is the exchange stiffness constant and K is the first order anisotropy constant of the hard phase. The ratio of the actual to the optimum grain size defines the ratio H_C/H_K (Refs. 1 and 4), where H_K is the anisotropy field of the hard phase.

By substituting Nd with Dy, which has higher anisotropy field, one would expect to get higher coercivities. The anisotropy constant K of Dy on the other hand is close to that of Nd so that the critical dimension for the soft phase is not expected to be very different. However in the $\text{Nd}_4\text{Dy}_2\text{Fe}_{87}\text{NbB}_6$ sample only moderate coercivities were obtained as shown in Fig. 4 where H_C is plotted as a function of annealing time. This can be attributed to the fact that Dy increases the crystallization temperature of the 2:14:1 phase⁵ requiring annealing conditions unfavorable to keeping the grain size of the soft phase close to the optimum size.

When substituting Nd with the nonmagnetic Y, the anisotropy of the hard phase is reduced. This of course is expected to lower the attainable coercivity but on the other hand δ and consequently the optimum grain size, will now be increased to values closer to the actual one. As shown in Fig. 4 for the $\text{Nd}_4\text{Y}_2\text{Fe}_{87}\text{NbB}_6$ sample H_C is reduced by more than the expected reduction in anisotropy when substituting 1/3 of Nd atoms by Y. In both cases it seems that the effect of the substitutions on the kinetics of the crystallization process does not permit a direct interpretation of the data in terms of

FIG. 5. TEM micrograph of a flash annealed $\text{Nd}_6\text{Fe}_{86.9}\text{Ag}_{0.1}\text{NbB}_6$ sample.

the expected changes in the anisotropy of the hard magnetic phase.

CONCLUSION

The optimum magnetic properties in $\text{Nd}_6\text{Fe}_{86.9}\text{T}_{0.1}\text{Nb}_6$ samples were obtained by annealing at 750 °C for a few minutes. Flashed annealed samples for shorter times gave similar results. However microstructural studies show that the grain size in these samples is greater than the theoretically predicted grain size for optimum coupling between the hard and the soft phase. Therefore one can expect even better properties in these samples by proper control of the crystallization procedure that would lead to smaller grain sizes.

Microstructural control of NdFeB cast ingots for achieving 50 MGOe sintered magnets

D. W. Scott, B. M. Ma, Y. L. Liang, and C. O. Bounds

Rhône-Poulenc, Rare Earths and Gallium, CN 7500, Cranbury, New Jersey 08512

The combination of chemical composition and microstructure of cast alloy has been found to be critical to the performance of NdFeB sintered magnets. Maximizing the amount of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase (or minimizing the amount of secondary phase) by reducing the Nd content more closely to the stoichiometric composition appears to be essential for obtaining high BH_{max} magnets. However, α -Fe precipitation has been found to increase with decreasing Nd content and severely hinders the development of high BH_{max} magnets. A two-step method, incorporating ingot casting and isothermal annealing, has been developed to minimize the amount of precipitated α -Fe in low Nd content alloys. This method provides a drastic improvement in the B_r and BH_{max} of sintered magnets obtained. By decreasing the Nd content to 13 at. % in the cast alloy, incorporating better particle control during fine milling, and controlling grain growth during sintering; magnets with a B_r of more than 14.5 kG and a BH_{max} of 50 MGOe have been consistently obtained. Furthermore, because of the reduction in the amount of Nd-rich grain boundary phase, a significant improvement in the corrosion resistance of magnets was also observed. © 1996 American Institute of Physics. [S0021-8979(96)37808-9]

I. INTRODUCTION

NdFeB-type permanent magnets are currently being used in an extensive array of applications where strong magnetic characteristics are required. With the rapid progression of technology, magnet manufacturers have expressed a desire to produce NdFeB magnets possessing a BH_{max} in excess of 45 MGOe.¹⁻³ While the chemical composition of a magnet is vital to obtaining optimum magnetic performance and corrosion resistance, microstructure is also important in dictating the magnet's overall quality. Recent trends have been aimed at adjusting the overall alloy composition from the original $\text{Nd}_{15}\text{Fe}_{79}\text{B}_6$ toward a more stoichiometric $\text{Nd}_2\text{Fe}_{14}\text{B}$ composition. By maximizing the amount of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase, manipulating grain alignment of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ crystals, controlling grain growth via sintering, magnets exhibiting a BH_{max} greater than 45 MGOe can be produced in production.⁴

While the use of a lower total rare earth content tends to improve the corrosion resistance of the magnet due to a reduction of the Nd-rich phase, it also allows for more α -Fe precipitation during solidification based on the Nd/B-Fe phase diagram.^{5,6} Precipitated α -Fe in the cast alloy makes powder reduction difficult in addition to hindering grain alignment, thus it could be detrimental to magnetic performance. In addition, α -Fe precipitation creates Nd-rich regions which are extremely susceptible to oxidation attack and magnet degradation. Controlling the amount of precipitated α Fe through improved casting techniques and isothermal annealing has become an important issue in alloy casting and magnet processing in order to achieve a BH_{max} of 50 MGOe.

In this article, we will quantify the amount of precipitated α Fe and other secondary phases in the cast alloys and relate them to the chemical composition and corrosion resistance in the sintered magnets. We will also present the effects of the amount of secondary phases on the energy product of sintered magnets.

II. EXPERIMENT

A set of three alloys cast to $\text{Nd}_x\text{Fe}_{94-x}\text{B}_6$ ($x=13,14,15$) were prepared by conventional vacuum induction melting and casting. Each alloy was isothermally annealed at 1050 °C for 8 h. Microstructure and isothermal magnetic analyses (ITMA), used to measure α -Fe precipitation, were evaluated for both as-cast and annealed ingots.⁶ The magnets used in this study were prepared and tested using the procedures detailed in previous reports.^{7,8}

III. RESULTS AND DISCUSSION

Figure 1 presents optical micrographs for NdFeB cast ingots at $\text{Nd}_x\text{Fe}_{94-x}\text{B}_6$ ($x=13,14,15$). Columnar grain growth in the cast ingots diminished as the total rare earth (TRE) content decreased from $x=15$ to $x=13$ as more precipitated α Fe appeared. This was most likely attributed to the increased residence time in the *liquid*+Fe phase region of the pseudo binary Fe-Nd-B phase diagram.⁹ In order to produce sintered NdFeB permanent magnets in excess of 50 MGOe, several secondary phases must be minimized by shifting the alloy composition toward a more stoichiometric $\text{Nd}_2\text{Fe}_{14}\text{B}$. These secondary phases were identified as the Nd-rich grain boundary phase,⁵ $\text{Nd}_{1+x}\text{Fe}_4\text{B}_4$ boron rich phase,¹⁰ neodymium oxide phases,³ and the α -Fe precipitation previously noted. Isothermal annealing was effective in reducing the amount of α -Fe precipitation in the cast alloy. Table I indicates the reduction in α -Fe precipitation for all three alloys. During isothermal annealing, α Fe reacts with the Nd-rich and $\text{Nd}_{1+x}\text{Fe}_4\text{B}_4$ phases to form $\text{Nd}_2\text{Fe}_{14}\text{B}$ which may explain the increase in the amount of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains as shown in Fig. 2.

After maximizing the $\text{Nd}_2\text{Fe}_{14}\text{B}$ matrix phase in the cast ingot, focus was directed at powder preparation and grain alignment to further increase magnetic remanence (B_r) and ultimately, energy product (BH_{max}). B_r was increased by

FIG. 1. Optical micrographs of $\text{Nd}_x\text{Fe}_{94-x}\text{B}_6$ as-cast ingots at 500 \times where (a) $x=15$, (b) $x=14$, and (c) $x=13$.

FIG. 2. Optical micrographs of $\text{Nd}_x\text{Fe}_{94-x}\text{B}_6$ annealed ingots at 500 \times where (a) $x=15$, (b) $x=14$, and (c) $x=13$.

minimizing powder oxidation and grain alignment (texture) as cited by several individuals as an important factor in achieving higher B_r and subsequently, higher BH_{max} in the final magnets.¹¹⁻¹³

Magnetic characterization was performed on the three sintered magnets listed in Table I and shown in Fig. 3. The inverse relationship between B_r and H_{ci} can be seen for magnets of varying TRE content. B_r increased steadily from 13.2 to 14.5 kG as TRE content decreased from $x=15$ to $x=13$. Microstructural evaluation and image analysis for the three magnets, shown in Fig. 4, explained the magnetic characteristics obtained for each magnet. The decrease in TRE content not only yielded a steady increase in BH_{max} but also drastically changed the magnet's microstructure. At $x=15$, a larger amount of secondary phase was present. Image analysis determined that the total secondary phases comprised nearly 30% of the entire sintered magnet with an average grain size of 10 μm as listed in Table I. Decreasing TRE content ($x=14$) generated a corresponding decrease in secondary phases. Image analysis measured the secondary phases to account for 21% of the total sintered magnet with

an average grain size of 9 μm . This trend continued with a further decrease in TRE ($x=13$) as the total secondary phases were calculated to be 17% of the magnet with an average grain size of 8 μm . It was critical to note that Nd content may be directly related to the average grain size in the sintered magnet. A decrease in Nd content, and consequently a reduction in the amount of Nd-rich grain boundary phase, may reduce the diffusion rate between grains which would minimize grain growth.

Chang expressed the importance of evaluating the texture for the cross section of a polished, sintered magnet by examining the x-ray diffraction pattern. Texture can be quantified by comparing the relative intensity ratio of the (006) peak to the (105) peak as shown in Fig. 5. Higher ratios are generally associated with optimum grain alignment. Optimization of texture is obtained by a combination of various steps: (1) increasing the percentage of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase by composition control, (2) decreasing particle size and particle size distribution of the precursor alloy powders, (3) minimizing grain growth. The ratio of the (006) to (105) peaks were calculated to be 1.50 for the 41 MGOe magnet, 1.55 for the

TABLE I. Characteristics of $\text{Nd}_x\text{Fe}_{94-x}\text{B}_6$ ingots and sintered magnets.

Nd content ($x=$)	$\alpha\text{-Fe}$ precipitation (wt %)		B_r (kG)	H_c (kOe)	H_{ci} (kOe)	BH_{max} (MGOe)	H_k (kOe)	Part. size (μm)	Grain size (μm)	Secondary phase (%)	Bulk corrosion (mg/cm ²)

FIG. 3. Hysteresis loops for 41, 45, and 50 MGOe sintered magnets.

45 MGOe magnet, and 1.57 for the 50 MGOe magnet.

Accelerated corrosion testing was also conducted on the three sintered magnets. The decrease in TRE content and minimization of the Nd-rich grain boundary phase tremendously reduced the regions for oxidation to occur as bulk corrosion resistance greatly improved for lower TRE containing magnets as shown in Table I. At $x=15$, bulk corrosion was measured to be 51.4 mg/cm^2 . Continuous improvements in bulk corrosion occurred with the decrease in Nd content to $x=14$ where corrosion was measured to be 6.2 mg/cm^2 with a further decrease to 0.0 mg/cm^2 at $x=13$.

Formation of $\text{Nd}(\text{Fe}_{1-y}\text{Co}_y)_2$ in rapidly quenched $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) alloys

Er. Girt, M. Koknaeva, and Z. Altounian

Centre for the Physics of Materials, Department of Physics, McGill University, 3600 University Street, Montréal, Québec H3A 2T8, Canada

X-ray diffraction patterns of overquenched $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) ribbons show fine grains of the 2-14-1 phase in an amorphous matrix. The ribbons, subsequently annealed at 975 K for 5 min, were investigated using quantitative x-ray structural analysis. The results indicate that in addition to the main 2-14-1 phase, all the samples have approximately 1 vol % of the γ -Nd phase. The existence of the $\text{Nd}(\text{Fe}_{1-y}\text{Co}_y)_2$ phase is established for $x \geq 0.25$ and its amount reaches up to 5.4 vol % for higher Co concentrations. From an interpolation of the measured lattice parameters of the 1-2 phase, the Co content is estimated to vary from $y=0.38$ to $y=0.58$ for this series of alloys. Using differential scanning calorimetry (DSC) the enthalpy of formation of the 1-2 phase in overquenched $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ ribbons is found to be about 3 kJ/mol. The activation energy necessary for the formation of the 1-2 phase, for the same composition, as determined from the Kissinger relation is 2.2 ± 0.1 eV. © 1996 American Institute of Physics. INTRODUCTION

The rapid solidification technique of melt spinning has been used to obtain Nd-Fe-B magnetic materials based on the 2-14-1 structure. Compositions which yield melt-spun ribbons with optimum magnetic properties are nonstoichiometric and are Nd rich.¹ This excess of Nd causes the formation of a suitable secondary phase, with a relatively low melting point, which plays a critical role in the magnet fabrication process. Apart from the excess of Nd, the Nd-Fe-B magnets often contain a certain amount of Co substituted for Fe to enhance the magnetic properties. It has been observed that for high Co concentrations ($x \geq 0.3$) in the R-rich R- $\text{Fe}_{1-x}\text{Co}_x$ -B alloys (R=Nd,Pr) the $\text{Nd}(\text{Fe,Co})_2$ phase appears.²⁻⁴ The NdCo_2 structure is a stable phase while the NdFe_2 is a high pressure phase which could be formed as a result of rapid solidification.⁵ In this study, we investigate the formation of the $\text{Nd}(\text{Fe,Co})_2$ phase in melt-spun $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) samples.

EXPERIMENTAL TECHNIQUE

The overquenched $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) ribbons were kindly supplied by C. D. Fuerst of General Motors. The ingots were prepared by induction melting in an argon atmosphere followed by melt spinning under argon using a wheel surface speed of 30 m/s. The ribbons were crushed and sieved to ensure that uniform flakes are selected. X-ray diffraction patterns of these flakes show very fine grains of the 2-14-1 phase as well as a large amount of the amorphous phase.⁶ A comparison of the enthalpy of formation of these ribbons with fully amorphous ribbons shows that the overquenched ribbons contain about 20% of crystalline 2-14-1 phase. Crystallization of $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) flakes was investigated using differential scanning calorimetry (DSC). Quantitative phase analyses of the ribbons before and after annealing were done using quantitative x-ray structural analysis. The

x-ray measurements were done on a Nicolet-Stöe powder diffractometer using graphite monochromated Cu $K\alpha$ radiation.

RESULTS AND DISCUSSION

The $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) flakes were crystallized by annealing at 970 K for 5 min. For quantitative analyses, the x-ray patterns of the annealed samples were fitted to the 2-14-1, γ -Nd (also known as the Nd-rich phase) and $\text{Nd}(\text{Fe}_{1-y}\text{Co}_y)_2$ structures. The results of the fitting for all compositions ($x=0-0.5$) indicate that besides the main 2-14-1 phase, all the samples have approximately 1 vol % of the γ -Nd phase. The formation of the $\text{Nd}(\text{Fe}_{1-y}\text{Co}_y)_2$ phase, however, is found to depend critically on the overall Co content of the ribbons. The volume fraction and lattice constants of the 1-2 phase obtained from the fitting are presented in Fig. 1. The existence of the 1-2 phase in the annealed samples is established for $x \geq 0.25$ and its amount seems to saturate at 5.4 vol % for $x \geq 0.3$. This is not unexpected as the Nd content is constant for all compositions

FIG. 1. The volume fraction and lattice constants of the $\text{Nd}(\text{Fe}_{1-y}\text{Co}_y)_2$ phase obtained from the fitting of the x-ray data of crystallized $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x=0-0.5$) ribbons. The concentrations of Co and y were estimated from the change in the lattice constants.

FIG. 2. X-ray diffraction scans of crystallized $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ribbons with $x=0.2$ and $x=0.25$.

and the amount of $\gamma\text{-Nd}$ is found to be independent of x . The lattice constant of the 1-2 phase decreases nearly linearly with increasing Co concentration. From an interpolation of the measured lattice constants of the NdFe_2 and NdCo_2 phases,^{5,7} we find that the Co content in $\text{Nd}(\text{Fe}_{1-y}\text{Co}_y)_2$ varies from a minimum of $y=0.38$ to a maximum of $y=0.58$ for this series of alloys. The x-ray patterns for the $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ samples ($x=0.2$ and 0.25) are shown in Fig. 2. For $x=0.25$, the presence of the $\text{Nd}(\text{Fe}_{0.62}\text{Co}_{0.38})_2$ phase is clearly seen.

Figure 3 shows the DSC thermoscan of the $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ ribbon sample heated at 40 K/min. Besides the crystallization of the amorphous phase at T_{x1} into the 2-14-1 phase, the DSC measurements show another exothermic reaction at T_{x2} . The inset of Fig. 3 gives an expanded view of the region where T_{x2} occurs. For structural studies, the $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ sample was heated at a

FIG. 3. DSC scans, at 40 K/min, for $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ ribbons. T_c is the curie temperature of the $\text{Nd}_2(\text{Fe}_{0.7}\text{Co}_{0.3})_{14}\text{B}$ phase, T_{x1} is the crystallization temperature of the $\text{Nd}_2(\text{Fe}_{0.7}\text{Co}_{0.3})_{14}\text{B}$ phase, and T_{x2} is the formation temperature of the $\text{Nd}(\text{Fe}_{0.573}\text{Co}_{0.427})_2$ phase. The inset represents an enlarged region from 890 to 990 K.

FIG. 4. X-ray diffraction scans obtained after heating the sample in the DSC at a rate of 40 K/min to (a) 900, (b) 920, (c) 940 K and subsequently cooled at a rate of 320 K/min.

rate of 40 K/min to the temperatures indicated by the letters a , b , and c in the inset of Fig. 3, and subsequently cooled at 320 K/min. X-ray diffraction results, displayed in Fig. 4, show that the 1-2 phase forms in the temperature region between a and c . Therefore, the exothermic reaction at T_{x2} represents the formation of the $\text{Nd}(\text{Fe}_{0.57}\text{Co}_{0.43})_2$ phase. From the enthalpy of the exothermic process at T_{x2} and the calculated amount of the 1-2 phase for $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ deduced from the quantitative x-ray analysis, we obtain a value of about 3 kJ/mol for the enthalpy of formation of the 1-2 phase. For the purpose of measuring the activation energy for the formation of the 1-2 phase, $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ samples were heated at different heating rates in the DSC. Using the Kissinger method,⁸ a value of 2.2 ± 0.1 eV for the activation energy of the 1-2 phase was obtained. It is worth mentioning that the amount of the 1-2 phase in the $\text{Nd}_{13.75}(\text{Fe}_{0.75}\text{Co}_{0.25})_{80.25}\text{B}_6$ sample diminishes after additional heating at 1170 K for 1 h. For the samples with high Co concentrations ($x \geq 0.3$) the 1-2 phase is stable at 1170 K.

CONCLUSION

The rapidly quenched $\text{Nd}_{13.75}(\text{Fe}_{1-x}\text{Co}_x)_{80.25}\text{B}_6$ ($x \geq 0.25$) samples contain the $\text{Nd}(\text{Fe,Co})_2$ phase after annealing at 975 K for 5 min. The amount of the $\text{Nd}(\text{Fe,Co})_2$ phase increases with the Co concentration and saturates at 5.4 vol % for $x=0.4$. The $\text{Nd}(\text{Fe,Co})_2$ phase forms after the crystallization of the $\text{Nd}_2(\text{Fe,Co})_{14}\text{B}$ phase for the rapidly quenched $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ samples. The enthalpy and activation energy of formation of the $\text{Nd}(\text{Fe,Co})_2$ phase in the $\text{Nd}_{13.75}(\text{Fe}_{0.7}\text{Co}_{0.3})_{80.25}\text{B}_6$ sample are 3 kJ/mol and 2.2 ± 0.1 eV, respectively.

Hard and soft magnetic properties of nanocrystalline Fe–Nd–Zr–B alloys containing intergranular amorphous phase (abstract)

A. Inoue, A. Kojima, A. Takeuchi, and T. Masumoto
Institute for Materials Research, Tohoku University, Sendai 980-77, Japan

A. Makino
Alps Electric Company, Ltd., Nagaoka, 940, Japan

The nanoscale crystalline and amorphous phases obtained by partial crystallization of an amorphous phase in rapidly solidified $\text{Fe}_{90}\text{Nd}_{7-x}\text{Zr}_x\text{B}_3$ alloys were found to exhibit rather good hard magnetic properties in the composition range below 3 at. % Zr and good soft magnetic properties in the range above 4 at. % Zr. The hard magnetic alloys consist of nanoscale bcc–Fe and bct– $\text{Fe}_{14}\text{Nd}_2\text{B}$ particles surrounded by the remaining amorphous phase, while the soft magnetic alloys are composed of bcc–Fe and remaining amorphous phases. The particle size is measured to be about 20 nm for the bcc–Fe phase and 15 nm for the $\text{Fe}_{14}\text{Nd}_2\text{B}$ phase for the former alloys and about 10 nm for the bcc–Fe phase for the latter alloys. The volume fraction of the remaining amorphous phase is evaluated to be about 20 to 30 at. % and the Nd and Zr contents are much higher than the nominal concentrations for the hard and soft magnetic alloys from the high-resolution TEM images and nanobeam compositional analyses. The remanence (Br), intrinsic coercivity (iHc), and maximum energy product are 1.24 T, 200 kA/m, and 88 kJ/m³, respectively, for the nanocrystalline $\text{Fe}_{90}\text{Nd}_5\text{Zr}_2\text{B}_3$ alloy annealed for 180 s at 1023 K, while the saturation magnetization (Bs), coercivity (Hc), and permeability at 1 kHz are 1.63 T, 16 A/m, and 7000, respectively, for the nanocrystalline $\text{Fe}_{90}\text{Nd}_2\text{Zr}_5\text{B}_3$ alloy annealed for 180 s at 923 K. The high Br and Bs values are presumably due to the magnetic coupling between bcc–Fe particles via the ferromagnetic intergranular amorphous phase and the large iHc for the alloy containing more than 4 at. % Nd is due to the exchange magnetic interaction between $\text{Fe}_{14}\text{Nd}_2\text{B}$ particles via ferromagnetic bcc–Fe and amorphous phases. The appearance of the rather good hard and soft magnetic properties for the same alloy series containing the high Fe content is extremely important for future development of nanocrystalline hard and soft magnetic materials. © 1996 American Institute of Physics. Melt-spun $\text{Pr}_2\text{Co}_{14}\text{B}/\text{Co}$ nanocomposite magnets

L. Withanawasam, I. Panagiotopoulos, and G. C. Hadjipanayis

Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

We have successfully prepared a new nanocomposite magnet consisting of a mixture of a magnetically hard $\text{Pr}_2\text{Co}_{14}\text{B}$ phase and a soft Co phase using the technique of melt spinning. The final microstructure with the above phases is formed after annealing the melt-spun ribbons through an intermediate transformation to the metastable TbCu_7 -type structure. Optimum coercivity of 4.3 kOe was observed in a sample with the composition $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ after heating above 775 °C.

INTRODUCTION

Recently, the new concept of nanocomposite magnets consisting of a fine mixture of magnetically hard and soft phase has attracted much attention because of its potential use for high performance, low cost permanent magnets.¹⁻⁵ The high reduced remanences and relatively high coercivity observed in melt-spun $\text{Nd}_4\text{Fe}_{77}\text{B}_{19}$ ribbons containing mostly soft Fe_3B with some hard $\text{Nd}_2\text{Fe}_{14}\text{B}$ led to the realization of this new material concept.^{6,7} A distinctive feature of such isotropic magnets is the observation of reduced remanence [M_r/M_s] greater than 0.5 which is a consequence of exchange coupling among the hard and soft grains. Previously, we have investigated and reported the properties of $\text{R}_2\text{Fe}_{14}\text{B}/\alpha\text{-Fe}$ nanocomposite magnets prepared by melt spinning.^{8,9}

In the present study, we have investigated the Pr-Co-B alloys consisting of $\text{Pr}_2\text{Co}_{14}\text{B}$ and Co phases. $\text{Pr}_2\text{Co}_{14}\text{B}$ with a high uniaxial anisotropy ($H_A=100$ kOe) and a saturation magnetization of 125 emu/g, and Co, with saturation magnetization of 160 emu/g, are suitable candidate phases for nanocomposite magnets. Despite the lower saturation magnetizations of $\text{Pr}_2\text{Co}_{14}\text{B}$ and Co compared to those of $\text{Pr}_2\text{Fe}_{14}\text{B}$ and Fe, the nanocomposites of $\text{Pr}_2\text{Co}_{14}\text{B}/\text{Co}$ showed a great potential for high temperature applications due to the higher Curie temperatures of $\text{Pr}_2\text{Co}_{14}\text{B}$ (720 °C) and hcp Co (1100 °C).

EXPERIMENT

Ingots with different compositions given by $\text{Pr}_x\text{Co}_{99-x-y}\text{Nb}_y\text{B}_y$ ($x=6,8$ and $y=6,8$) were prepared by arc melting the constituent elements in argon atmosphere. These compositions were selected to achieve a nanocomposite material in which the hard $\text{Pr}_2\text{Co}_{14}\text{B}$ phase content is higher than 50 wt %. Pieces of the ingot were melt-spun from a quartz tube having an orifice diameter of about 1 mm. Wheel speeds in excess of 45 m/s were used. The resulting ribbons were studied using differential scanning calorimetry (DSC) and differential thermal analysis (DTA) for possible phase transformations. X-ray diffraction ($\text{Cu } K_\alpha$) was used to identify the phases present. The hysteresis loops were measured in a vibrating sample magnetometer (VSM) with a maximum field of 20 kOe. Selected samples were also measured in a SQUID magnetometer with a maximum field of 55 kOe. The coercivity of the samples was optimized through annealing at temperatures in the range of 650–900 °C and times between 4 and 60 min.

RESULTS AND DISCUSSION

X-ray diffraction was used to determine the structure of as-spun ribbons. The diffraction patterns showed that the ribbons with Co content less than 85% were amorphous/nanocrystalline in structure. The ribbons containing more than 85 at. % of Co were crystalline with strong reflections due to fcc Co.

Calorimetric studies were performed on the as-spun samples using differential thermal analysis to determine the phase transformation temperatures. Two such thermal scans on ribbons with composition $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ and $\text{Pr}_8\text{Co}_{85}\text{Nb}_1\text{B}_6$ are shown in Fig. 1. These traces consist of three exothermic peaks; a broad peak with $T_{\text{peak}} < 600$ °C, a sharp exotherm near 645 °C, and another peak at $T_{\text{peak}} > 760$ °C. The low-temperature exotherms are due to the amorphous to crystalline structural transformations.

Samples annealed at temperatures close to 650 °C were examined through x-ray diffraction and revealed the pattern shown in Fig. 2. The major reflections of this pattern can be indexed to a hexagonal structure of the type TbCu_7 . Thus, after crystallization the samples contain a majority phase of the TbCu_7 -type along with some minority phases as indicated by the XRD pattern including fcc cobalt.

When these samples were annealed at temperatures above the higher temperature exotherms ($T_{\text{peak}}=760$ and 775 °C), the metastable TbCu_7 -type structure transformed to

FIG. 1. DTA traces obtained for as-spun $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ and $\text{Pr}_8\text{Co}_{85}\text{Nb}_1\text{B}_6$ samples at a scanning rate of 10 °C/min showing three exothermic peaks.

FIG. 2. XRD pattern of a $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ sample annealed at 650 °C indicating the presence of TbCu_7 -type and fcc Co structures.

the intended mixture of $\text{Pr}_2\text{Co}_{14}\text{B} + \text{Co}$ (both fcc and hcp) phases. This is evident from the XRD pattern of a $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ sample annealed at 775 °C shown in Fig. 3. Hence, we establish that a mixture of $\text{Pr}_2\text{Co}_{14}\text{B}$ and Co phases can be prepared by the conventional metallurgical process of rapid quenching.

Magnetic hysteresis studies showed that the as-spun samples are soft and develop a coercivity of about 500 Oe after annealing at 650 °C (to the metastable TbCu_7 -type structure). The development of coercivity with annealing temperature and time was further investigated. A summary of these results are presented in Figs. 4 and 5 for the $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ and $\text{Pr}_8\text{Co}_{85}\text{Nb}_1\text{B}_6$ samples, respectively. As mentioned before, the coercivity is negligible for annealing at temperatures below 775 °C due to the absence of the hard $\text{Pr}_2\text{Co}_{14}\text{B}$ phase. When the annealing temperature is raised above 775 °C, large coercivities develop after a relatively long annealing time of the order of an hour. This time can be reduced by increasing the annealing temperature to attain

FIG. 3. XRD pattern of a $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ sample annealed at 775 °C indicating the presence of $\text{Pr}_2\text{Co}_{14}\text{B} + \text{Co}$ phases.

FIG. 4. Coercivity of $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ as a function of annealing time at different annealing temperature.

coercivities close to those resulting from the 775 °C anneal. This behavior is quite different from what we have observed in the $\text{Pr}-\text{Fe}-\text{Nb}-\text{B}$ system. Namely, the optimum annealing time is lower than 10 min, and the optimum temperature is as close to the transition temperature at which the hard phase appears. Furthermore, in the Fe system even a small excess of temperature and time leads to a considerable degradation of the coercivity in contrast to the behavior observed in $\text{Pr}_2\text{Co}_{14}\text{B}/\text{Co}$ samples.

The hysteresis loop of a coercivity optimized $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ with a coercivity of 4.3 kOe is shown in Fig. 6. The magnetization measured under a maximum field of 20 kOe is 90 emu/g with a reduced remanence of 0.60. The observation of such coercivity and reduced remanence are believed to be a consequence of exchange coupling between the hard and soft phases of the magnet.⁷

In a nanocomposite magnet the coercivity depends on the ratio of hard to soft phase content as well as on the microstructure. The above data seem to indicate that for the

FIG. 5. Coercivity of $\text{Pr}_8\text{Co}_{85}\text{Nb}_1\text{B}_6$ as a function of annealing time at different annealing temperatures.

FIG. 6. Hysteresis loop of a coercivity optimized $\text{Pr}_8\text{Co}_{83}\text{Nb}_1\text{B}_8$ sample showing a room temperature coercivity of 4.3 kOe.

Pr-Co-B system a microstructural development preceding the structural transformation (from soft TbCu_7 -type to $\text{Pr}_2\text{Co}_{14}\text{B}$) is required to optimize coercivity. However, the above premise has to be verified through microstructural investigations.

Samples containing 6 at. % of Pr resulted in moderate coercivities of only 2.0 kOe. The existence of a large crystalline fraction (Co) in the as-spun ribbons of these samples may be responsible for this poor coercivity.

CONCLUSION

We have successfully prepared a melt-spun composite magnet consisting of a mixture of $\text{Pr}_2\text{Co}_{14}\text{B}$ and Co phases having coercivities as high as 4.5 kOe.

Hydrogen induced corrosion mechanism in NdFeB magnets

A. S. Kim, F. E. Camp, and T. Lizzi

Crucible Research Center, Crucible Materials Corporation, 6003 Campbells Run Road, Pittsburgh, Pennsylvania 15205-1022

An investigation was conducted comparing the corrosion behavior of NdFeB magnets in flowing hydrogen and in the heat and humidity of an autoclave. The results show that corrosion is both macroscopically and microscopically similar in both environments. In both cases, the corrosion progressed most rapidly in those areas where the magnetic orientation of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ matrix grains was perpendicular to the outer surface. A corrosion mechanism involving the reaction of hydrogen—either as a pure gas or as a by-product of the decomposition of water vapor—with the neodymium-rich grain boundary phase is proposed. © 1996 American Institute of Physics. [S0021-8979(96)38108-6]

I. INTRODUCTION

The corrosion of Nd-Fe-B-type magnets has long been associated with exposure to humidity.¹⁻⁴ It is expected that the water vapor reacts with the Nd-rich grain boundary phase to cause the corrosion.³ Thus, the application of moisture barriers such as epoxy or metallic coatings have proven effective in reducing the rate of corrosion of Nd-Fe-B magnets.²⁻⁴ Further, the corrosion resistance is improved by stabilization of the Nd-rich grain boundary phase by the addition of alloying elements.⁴⁻⁷ However, the mechanism involved in the corrosion of Nd-Fe-B-type alloys on exposure to humidity has not been settled. The present paper deals with an investigation into humidity-related corrosion mechanism.

II. EXPERIMENT

The magnets used in this study were prepared by standard powder metallurgical sintering techniques from an alloy having a chemical analysis of (weight percent): 30.8 Nd, 3.33 Dy, 64.6 Fe, 1.09 B, 0.07 Al, 0.08 C, and 0.04 O. The sintered magnets were machined to disks approximately 14 mm diameter by 7 mm thick. Two types of environmental corrosion testing were performed on unmagnetized samples. Autoclave tests were used to expose the magnets to a hot, humid environment. In these tests, the magnets were placed in autoclaves where a pool of water was vaporized to produce a pressure of 10–15 psi and a temperature of 110–115 °C. This method has proven to be a convenient way of estimating the susceptibility of NdFeB magnets to atmospheric corrosion.^{1,2} Hydrogen exposure testing was accomplished by placing the magnets in laboratory glassware under flowing hydrogen at atmospheric pressure at room temperature. Corroded samples were mounted and cross-sectioned parallel to the magnetic direction. The samples were metallographically polished and then examined by light microscopy and by scanning electron microscopy (SEM).

III. RESULTS AND DISCUSSION

The magnets in this study were subjected to either flowing hydrogen or to a 110–115 °C humid atmosphere in a 96 h autoclave test. Figure 1 shows that the corrosion was inter-

granular, i.e., along the Nd-rich grain boundary phase, for both the hydrogen and the humidity exposure test samples.

Also, for both testing conditions, the resulting corrosion occurred primarily on the pole faces of the magnets. The corrosion progressed in the direction of the magnetic orientation as shown in Fig. 2. These results agree with the observation of McGuinness *et al.*⁸ that both hydrogen and humidity induced corrosion progressed along the magnetic direction from the pole faces in aligned samples but occurred generally from all surfaces on isotropic samples.

FIG. 1. SEM micrographs of (Nd-Dy)-Fe-B magnets subjected to (a) autoclave test and (b) hydrogen exposure. Magnetic orientation is normal to the magnet outer surface.

FIG. 2. Cross section of the (Nd-Dy)-Fe-B magnets subjected to (a) autoclave test and (b) hydrogen exposure. Magnetic orientation is in the vertical direction.

Metallographic examination reveals that the corrosion was related to the local orientation of the matrix $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains as illustrated in Fig. 3. The reason for this is related to the morphological arrangement of the $\text{Nd}_2\text{Fe}_{14}\text{B}$ matrix grains. The matrix grains are of a tetragonal structure whose magnetic axis is along the c axis. As is evident in Fig. 1, the matrix grains are generally rectangular or brick shaped in cross section with the c axis several times shorter than the a axis. In magnetically aligned samples, the matrix grains become arranged in a more or less layered pattern. This results in the Nd-rich grain boundary phase also being arranged in layers. During corrosion or decrepitation, the transformation of the Nd-rich grain boundary phase to a hydride causes it to expand creating local stresses. The mechanical effect of the expansion is greatest along the continuous layers of the Nd-rich phase. Thus, the disadhesion of the matrix grains occurs in layers and the corrosion progresses along the local direction of magnetization as these layers spall off.

The similarities between the corrosion caused by exposure to the two types of atmospheric conditions tested infers a common corrosion mechanism. Since the hydrogen exposure presents hydrogen as the sole reactant species, it is logical that hydrogen would be involved in a common corrosion mechanism. Hydrogen may be generated in the autoclave testing from the decomposition of water vapor:

The hydrogen may then diffuse into the magnet and become a reactant with the Nd-rich grain boundary phase causing the

FIG. 3. Illustrations of how the corrosion followed the local orientation of the matrix grains in a similar fashion in both autoclaved and hydrogen exposure samples. (a), (b) Area of autoclaved sample at two magnifications; (c), (d) area of hydrogen exposed sample at two magnifications.

observed corrosion:

Thus, the corrosion mechanism for NdFeB magnets in the heat and humidity of the autoclave test starts with a surface reaction of water vapor with the Nd-rich grain boundary phase. Then, as the hydrogen diffuses along the grain boundaries into the interior of the magnet, the hydrogen reacts with the Nd-rich grain boundary phase to cause a volume expansion of the grain boundary phase. This results in the dislodging of the Nd₂Fe₁₄B matrix phase grains and decrepitation occurs. This same phenomenon also occurs with the exposure of the magnets to pure hydrogen, except that the initial reaction of the moisture to form the hydrogen is replaced by a dissociation of molecular hydrogen.

Hydrogen is also known to enter into the Nd₂Fe₁₄B matrix phase.⁹ However, as Harris has noted,¹⁰ elevated temperatures or pressures are necessary for this to occur. Unless the rate of the exothermic reaction of the hydrogen with the Nd-rich phase is sufficient to locally raise the temperature to the necessary level, matrix phase adsorption of hydrogen, although not unimportant, would probably not dominate in humidity-related corrosion.

On the other hand, there is collaborative data supporting the conclusion that the hydrogen reaction with the Nd-rich grain boundary phase is the predominant mechanism in the humidity-related corrosion of Nd-Fe-B-type magnets. First, a strong correlation has been established between an increase in the total rare earth level—and, therefore, an increase in the amount of Nd-rich phase—and an increase in the corrosion rate.¹¹ Also, as noted earlier, alloying additions to the Nd-rich grain boundary phase can greatly reduce the bulk corrosion rate.

IV. CONCLUSIONS

The corrosion of NdFeB magnets in hot, humid autoclave and flowing hydrogen environments was found to be

similar both macroscopically and microscopically. In both cases, the corrosion progressed most rapidly in those areas where the magnetic orientation of the Nd₂Fe₁₄B matrix grains was perpendicular to the outer surface. Hydrogen, introduced either as a gas or as a product of a reaction of water vapor with the Nd, diffuses along the grain boundaries and reacts with the Nd-rich grain boundary phase. This reaction causes an expansion of the Nd-rich grain boundary phase which in turn dislodges the NdFeB matrix phase grains leading to magnet decrepitation. Observations of the effect of various alloying elements supports the supposition that the hydrogen reaction which causes the corrosion is primarily with the Nd-rich grain boundary phase.

Magnetic properties and transmission electron microscopy microstructures of exchange coupled Nd_{12-x}Fe_{82+x}B₆ melt spun ribbons

W. C. Chang and D. M. Hsing

Department of Physics, National Chung Cheng University, Ming-Hsiung, Chia-Yi, Taiwan, Republic of China

The nanocomposite melt spun ribbons of the alloys Nd_{12-x}Fe_{82+x}B₆ ($x=0, 2.5, 3$, and 4) have been prepared by rapid quenching and/or post heat treatment. In the alloy with $x=0$, homogeneous grain morphologies were obtained at the lower wheel speed ($18 \text{ m/s} \leq \text{Sw} \leq 25 \text{ m/s}$) to result in a strong exchange coupling effect between Nd₂Fe₁₄B and α -Fe grains, the magnetic properties of $\text{Br}=9.6 \text{ kG}$, $iH_c=7.7 \text{ kOe}$, and $(BH)_{\text{max}}=18 \text{ MGOe}$ was achieved. In the alloys with $x=2.5, 3$, and 4 , exchange coupling effect is also found and the best magnetic properties of $\text{Br}=11.4 \text{ kG}$, $iH_c=6.3 \text{ kOe}$, and $(BH)_{\text{max}}=19 \text{ MGOe}$ are achieved in the alloy ribbons with $x=2.5$ quenched at a wheel speed of 18 m/s without any post heat treatment. Inasmuch as the crystallization temperature of the ribbons increased with decreasing the Nd content, the microstructures, the size and volume fraction of the α -Fe and Nd₂Fe₁₄B phases evaluated by transmission electron microscopy observation, of the above alloy ribbons were dominated by the Nd content, the wheel speed and the heat treatment temperature apparently. As a result, the exchange coupling effect and the magnetic properties of the ribbons were strongly affected. © 1996 American Institute of Physics. [S0021-8979(96)38208-2]

I. INTRODUCTION

Recently, nanocomposite magnets with a soft magnetic phase embedded in hard magnetic matrix phase have been of interest due to their high magnetization without excessive loss of coercivity.^{1,2} In the Nd₂Fe₁₄B type nanocomposite magnets, two type of composites, α -Fe/Nd₂Fe₁₄B,³ and Fe₃B/Nd₂Fe₁₄B,^{1,4} have been widely studied. In this article, we have studied the alloys around the composition of Nd₂Fe₁₄B, i.e., Nd_{12-x}Fe_{82+x}B₆, to determine the effect of Nd content on the microstructure, the exchange coupling effect and the magnetic properties of the nanocomposite ribbons. Finally, the relationship between the size and volume fraction between α -Fe and Nd₂Fe₁₄B phases, identified with transmission electron microscopy (TEM), and the magnetic properties of the ribbons will be presented and discussed.

II. EXPERIMENT

The starting materials of the Nd_{12-x}Fe_{82+x}B₆ ($x=0, 2.5, 3$, and 4) ingots, 250 g for each, were prepared by a vacuum induction furnace. The composition and alloy abbreviation of each alloy is listed in Table I. The ingots were crushed and small pieces of each (about 2 g) were used for melt spinning. The wheel speed of the melt spinner was set in the range from 18 to 35 m/s during preparation of the melt spun ribbons. The crystallization temperature for each over-quenched alloy ribbon was measured with a differential thermal analyzer (DTA). The ribbons were subsequently heated treated

at 700 or 750°C for 10 to 30 min in order to improve the microstructures and magnetic properties. The crystallinity of the as-quenched ribbons and the heated treated ribbons were investigated by a x-ray diffractometer with Cu $K\alpha$ radiation. The ribbons were first magnetized with a pulse magnetic field of 60 kOe , and then the magnetic properties were measured by a vibrating sample magnetometer (VSM) with an applied field of 12 kOe . The microstructures of the ribbons were observed by a transmission electron microscope; the grain size of the α -Fe and Nd₂Fe₁₄B phases and their volume fractions were measured from TEM photographs for correlating with their magnetic properties.

III. RESULTS AND DISCUSSION

Table II exhibits the glass formation temperature (T_g) of the over-quenched $N1, N2, N3$, and $N4$ alloy ribbons measured from the DTA curves. It shows that the value of T_g increases with decreasing the Nd content of the ribbons. Due to the difference of the glass formation temperature in those four alloy ribbons, the first two alloy ribbons in this study, $N1$ and $N2$, were heat treated at 700°C , while the latter two alloy ribbons, $N3$ and $N4$, were heat treated at 750°C for various times to obtain suitable grain sizes and also proper magnetic properties. From phase diagram, the possible phases for the $N1$ ribbon after crystallization are α -Fe and Nd₂Fe₁₄B, whereas a small amount of Fe₃B might appear in $N2, N3$, and $N4$ ribbons. However, from our x-ray diffraction patterns and TEM micrographs, it is rather difficult to

FIG. 1. The magnetic properties of the as-spun alloy ribbons melt quenched at different wheel speed.

prove the existence of Fe_3B phase in these ribbons. The difficulty may be due the very small volume fraction of Fe_3B , so that one cannot detect it easily.

A. Magneties properties of the ribbons

The magnetic properties of the as-quenched ribbons are strongly dependent upon the alloy composition and the wheel speed (S_w) during melt spinning. The Br , iHc , and $(BH)_{\text{max}}$ are shown in Fig. 1. Note that worse magnetic properties were measured on the $N3$ and $N4$ alloy ribbons quenched at or exceeding 20 m/s since they were amorphous, which was confirmed with x-ray diffraction analysis. On the other hand, the $N1$ and $N2$ alloy ribbons might be well crystallized already at a wheel speed equal to or less than 25 m/s resulting in a quite excellent magnetic properties, especially for the case of $N2$ alloy ribbons. For example, the magnetic properties of $Br=11.4$ kG, $iHc=6.3$ kOe, and $(BH)_{\text{max}}=19$

FIG. 2. The best magnetic properties of the $\text{Nd}_{12-x}\text{Fe}_{82+x}\text{B}_6$ ($x=0, 2.5, 3$, and 4) alloy ribbons under various condition of heat treatment.

FIG. 3. TEM micrographs and the selected area diffraction (SAD) patterns of the $N1-25$ m/s ribbon heat treated at 700 °C for 30 min [(a) and (b)] and the $N4-25$ m/s ribbon heat treated at 750 °C for 30 min [(c) and (d)].

MGOe was achieved in the $N2$ ribbons quenched at a wheel speed of 25 m/s, these values are higher than the values of the commercial NdFeB MQ powders. From the higher remanence than 8 kG, the maximum Br value of isotropic $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase that predicted from a Stoner-Wohlfarth model, one can easily conclude the existence of the exchange coupling effect between the hard magnetic phase, $\text{Nd}_2\text{Fe}_{14}\text{B}$, and soft magnetic phase, $\alpha\text{-Fe}$.³

After a suitable heat treatment, the magnetic properties of $N1$, $N3$, and $N4$ alloy ribbons were drastically improved. However, heat treatments did not improve but deteriorated slightly the magnetic properties of $N2$ alloy ribbons. As it is known that the magnetic properties of the nanocomposite ribbons are strongly dependent upon the size and the volume fraction of the soft and hard magnetic phases,^{5,6} one can speculate that the grain sizes are very fine after melt spinning of $N1$, $N3$, and $N4$ alloys. The subsequent heat treatment improves their microstructures and therefore enhances their magnetic properties. In the case of $N2$ ribbons, owing to the grain sizes are already well established after melt spinning at or lower than 25 m/s, further heat treatment may promote $\alpha\text{-Fe}$ grains, also $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains, growing beyond the critical size, i.e., $d \approx 10.4$ nm,⁷ of the best exchange coupling interaction. Figure 2 shows the best magnetic properties of the above four alloy ribbons after their best heat treatment ($N1$, $N3$, and $N4$) or without any subsequent treatment ($N2$). From Fig. 2 it can be seen that the magnetic properties, especially iHc and $(BH)_{\text{max}}$, have a sharp transition

TABLE III. The grain size and vol. fraction of α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ phases and the magnetic properties of various alloy ribbons subjected different heat treatment.

Alloy	S_w (m/s)	Heat treatment	$D_{\alpha\text{-Fe}}/D_{2:14:1}$ (nm/nm)	α -Fe (vol %)	Br (kG)	iH_c (kOe)	(BH)max (MGOe)
N1	25	700 °C, 30 min	20/70	8	9.5	8	18
N1	30	700 °C, 30 min	40/120	8	7.8	7.3	9.4
N2	18	...	15/50	15	11	6.3	18
N2	35	700 °C, 20 min	50/250	15	9	2.8	7.2
N3	18	750 °C, 20 min	35/70	25	10.9	4.1	11.7
N4	25	750 °C, 30 min	50/80	35	9.9	2.8	7.8

from N2 to N3. For N1 and N2 alloy ribbons, (BH)max over 18 MGOe can be achieved, but only 12 and 11 MGOe were obtained in N3 and N4 alloy ribbons, respectively. The reason of this big difference in magnetic properties will be studied from their microstructure observation as follows.

B. Microstructure analysis of the ribbons

The microstructures of various alloy ribbons with or without heat treatment have been studied. Two special cases are shown in Fig. 3. Figures 3(a) and 3(b) are the TEM micrographs and the selected area diffraction (SAD) patterns of alloy ribbon N1 quenched at 25 m/s then followed with 700 °C heat treating for 30 min, and Figs. 3(c) and 3(d) are that of the alloy ribbon N4 quenched at 25 m/s followed with 750 °C heat treating for 30 min. For the former alloy ribbon, the size of the α -Fe phase (as arrow A indicates) is quite small, also the volume fraction of it is low in comparison with that of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase (as arrow B indicates). For the latter alloy ribbon, the size and volume fraction of the α -Fe phase apparently increase. The size of the α -Fe phase is almost identical to that of $\text{Nd}_2\text{Fe}_{14}\text{B}$ phase. As mentioned previously, the Fe_3B phase is the third phase that is most likely to form in this alloy; unfortunately, it is not easy to distinguish between Fe_3B , if any, and α -Fe phases simply from their shape and from their compositions analyzed with energy dispersive x-ray analyzer.

Table III lists the grain size and volume fraction ratio of the α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ phases, evaluated from TEM micrographs, and the magnetic properties of various alloy ribbons subjected different heat treatment. It can be found that a small α -Fe grain size (≤ 20 nm) is accompanied with a high Br, iH_c , and (BH)max for the ribbons of N1–25 m/s and N2–18 m/s, even though it is larger than 10.4 nm of the calculated critical size for strongest exchange coupling. The grain size of $\text{Nd}_2\text{Fe}_{14}\text{B}$ (50–70 nm) in these two ribbons seems not to affect the magnetic properties. The increases in grain size of both the α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ phases in the ribbons of N1–30 m/s and N2–35 m/s due to heat treatment results in the reduction of Br, iH_c , the squareness of the 2nd quadrant demagnetization curve and (BH)max drastically. Since reducing the Nd content in the alloy ribbons may retard the crystallization tendency, a higher heat treatment tem-

perature is needed for the low Nd containing alloy ribbons, N3 and N4, to crystallize, leading to very rapidly growing α -Fe grains (50 nm for N4–25 m/s ribbon annealed at 750 °C for 30 min). Also, the volume fraction of α -Fe increases with the decrease of Nd content, the exchange coupling effect between α -Fe and $\text{Nd}_2\text{Fe}_{14}\text{B}$ phases is therefore rapidly decreased.⁶ This is the reason why we could not easily obtain excellent magnetic properties of melt spun ribbons in the low Nd containing alloys, i.e., N3 and N4.

IV. CONCLUSION

The nanocomposite melt spun ribbons of the alloys $\text{Nd}_{12-x}\text{Fe}_{82+x}\text{B}_6$ ($x=0, 2.5, 3$, and 4) can be prepared by direct rapid quenching with or without a proper post heat treatment. The crystallization temperature of the ribbons increases with decreasing the Nd content of the alloy so that their microstructures and magnetic properties are affected. For the alloys with $x=0$ and 0.25, a microstructure with fine α -Fe, ≤ 20 nm, embedded in $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains can be easily obtained, the magnetic properties of Br=11.4 kG, $iH_c=6.3$ kOe, and (BH)max=19 MGOe result. For the alloys with $x=3$ and 4, a microstructure with a larger volume fraction and coarser α -Fe, ≥ 50 nm, coexisting with coarser $\text{Nd}_2\text{Fe}_{14}\text{B}$ grains is easily seen when the ribbons subjected to subsequent heat treatment. The exchange coupling effect between magnetic hard and soft phases is drastically decreased.

Spring magnets consist of a mixture of exchanged coupled, hard and soft magnetic phases and exhibit improved energy products and remanence. In this study, magnets containing a mixture of $\text{Nd}_2\text{Fe}_{14}\text{B}$ and Fe_3B have been fabricated using melt spinning under either Ar or He atmospheres.¹ In addition, samples have been heat treated using conventional (furnace) annealing and flash annealing techniques. Magnetic measurements using VSM confirm good spring magnet behavior for all the conventionally annealed samples and for samples flash annealed for $t < 30$ s and $T < 750$ °C. X-ray diffraction reveals that α -Fe, Fe_3B , and $\text{Nd}_2\text{Fe}_{14}\text{B}$ are present in different amounts depending on the annealing conditions. Transmission electron microscopy shows differences in grain size, crystallinity, and phase distribution. Lorentz electron microscopy reveals the influence of the microstructure on the magnetic domain structure. These results are correlated with the observed magnetic properties. © 1996 American Institute of Physics. [S0021-8979(96)63908-9]

In bulk permanent magnets, the extrinsic properties relating to the microstructure determined the level of hard magnetic properties that is actually achieved. Many researchers have worked on the microstructure property relationships in the $\text{Nd}_2\text{Fe}_{14}\text{B}$ (2-14-1) system but, in general, the approach has been to analyze the microstructure of materials which have been shown to have good magnetic properties rather than to study the effect of alloy additions on the metallurgical properties of the system. The microstructure which is obtained under a given set of processing conditions is highly dependent on the solidification behavior of the alloy, as well as grain growth phenomena. Alloy additions which effect the solidification behavior of the melt and then form precipitates which pin grain boundaries, and therefore control grain size, should be valuable in producing the uniform microstructure required for good magnetic properties. A number of refractory metal carbides perform both of these functions. The carbides have a reasonable degree of solubility in the 2-14-1 melt and, under conditions of reasonable rapid solidification, a degree of metastable solubility in the 2-14-1 phase. However, there is very limited equilibrium solid solubility in the 2-14-1 phase so that the intrinsic magnetic properties are not effected. The addition of these materials to 2-14-1 results in a factor or three reduction of the quench rate required to produce amorphous material. In addition, the crystallization temperature of the glass is enhanced leading to enhance nucleation and finer grain size during crystallization. Finally refractory metal carbide precipitates decorate the grain boundaries of the crystallized material inhibiting grain growth. Transition metal carbide formation, solid and liquid solubility, effects on solidification, nucleation, and grain growth will be discussed. © 1996 American Institute of Physics. A detailed study of the microstructure and composition in hot-pressed (MQ-2) and die-upset (MQ-3) magnet alloys based on the $\text{Nd}_2\text{Fe}_{14}\text{B}$ composition, utilizing high resolution and analytical transmission electron microscopy, is reported. The initial magnetic properties of the two samples show different behaviors, which are attributed to the difference in the anisotropy of the grain structure and the grain boundaries. The hot-pressed sample shows faceted grains of the 2-14-1 phase, while die-upset sample shows plate-like grains, together with larger equiaxed grains that contain a speckling of precipitates in the grain interior. The grain structure and composition remain rather similar in the two samples. The grain boundary phase averages $\sim 1\text{--}10$ nm in width. The thicker grain boundaries are Nd-rich, while the thinner grain boundaries in the hot-pressed sample exhibit an Fe-rich composition near that of the NdFe_3 phase. Nd-rich phases are found at the grain boundary junctions of both samples, with the Nd:Fe ratio near 7:3 in the die-upset sample, and up to 3:2 in the hot-pressed sample. The significance of the microstructure and the grain boundary phases on the magnetic behavior in the two samples is discussed. © 1996 American Institute of Physics. [S0021-8979(96)38308-9]

INTRODUCTION

Dependence of the magnetic properties in melt-quenched and die-upset magnet alloys on the microstructure and composition is well known; mechanisms for demagnetization in these alloys however is still an area of active debate. Models that have been proposed to explain the behavior of die-upset magnetic alloys include strong pinning model,^{1,2} nucleation model,³ and microcrystalline model.⁴ A review of these models is given by Herbst.⁵ Observation of the domain structures of a thin die-upset magnet sample in an electron microscope using the Lorentz technique indicates that magnetization proceeds by domain wall motion restricted by pinning at grain boundaries,⁶ while investigations on interaction mechanisms by analysis of the time-dependent magnetizing curves after thermal demagnetization agrees with the nucleation-controlled mechanism.⁷ Preliminary microstructural studies of die-upset NdFeB samples with the nominal composition $\text{Nd}_{13.75}\text{Fe}_{80.25}\text{B}_6$ show the presence of an Fe-rich phase at the grain boundaries.^{8,9} It was proposed that this phase provides possible exchange coupling between grains and potential reversed domain nucleation sites. In this article, we present microstructure and phase analyses of hot-pressed (MQ-2) and die-upset (MQ-3) magnet alloys studied by transmission electron microscopy (TEM). The relationship between the observed microstructure and magnetic properties, and the effects of the secondary and grain boundary phases on the reversal mechanisms in these materials are discussed.

EXPERIMENTAL TECHNIQUES

The magnet alloys were obtained from the General Motors Research and Development Center. Overquenched melt-spun ribbons were consolidated at 750 °C to form the hot-pressed sample; and further deformed at 800 °C to produce

the oriented die-upset magnet.¹⁰⁻¹² The magnetic measurements were performed with a quantum design SQUID magnetometer of thermally demagnetized samples.⁸ For TEM examination, the materials were ultrasonically cut into 3 mm discs, mechanically thinned and dimpled, and then ion-milled at liquid nitrogen temperature until transparent to the electron beam. They were studied in JEOL 200CX microscopes, operating at 200 kV. The electron beam size used for microanalysis ranged from 10 to 15 nm in diameter.

RESULTS

Comparison of the magnetic data of the two samples measured at 77 °C (350 K) is shown in Figs. 1(a) and 1(b). In general, while both samples display a linear increase in properties with applied field, the die-upset sample acquires its saturation magnetization M_s at lower maximum field than does the hot-pressed sample [Fig. 1(a)]. The initial susceptibility of the hot-pressed sample is substantially lower than that of the die-upset sample, indicating that it is much more difficult to magnetize the former. The hot-pressed sample reaches a much higher coercivity value, but the remanence is poor.

The microstructure of the hot-pressed sample is shown in Fig. 2. It exhibits mostly faceted 2-14-1 nm-sized grains with low-contrast grain boundary regions typically on the order of 2–3 nm [Fig. 2(a)]. Transmission electron diffraction does not reflect any preferred orientations in the grains, similar to results from transmission neutron scattering and transmission x-ray diffraction of similar samples.¹³ Shown in the inset is a typical energy dispersive x-ray (EDX) spectrum from the main 2-14-1 phase. Since boron could not be detected with this technique, the ratio of Nd to Fe in this phase is 1:7. EDXs analysis of the thin grain boundary regions indicates an Fe-rich phase with Nd:Fe ratio between 1:4 and

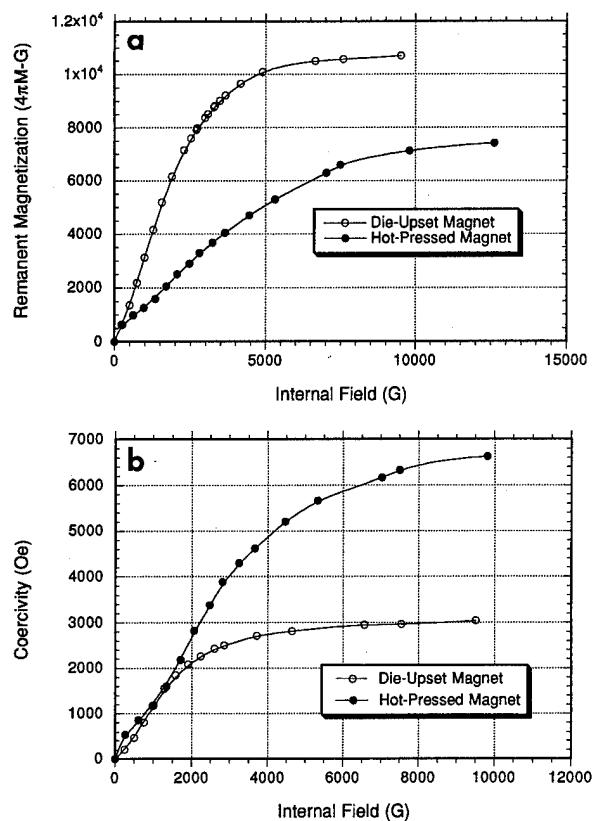

FIG. 1. Development of (a) remanent magnetization B_R and (b) coercivity H_{ci} , with internal field at $T = 77^\circ\text{C}$ (350 K).

1:5, as has been reported in previous studies on related die-upset magnets.^{8,9} The microstructure also contains pockets of noticeably different contrast with sizes up to 10 nm at the junctions between many grains, suggestive of a different phase material. Figure 2(b) shows a high-resolution image of such a grain junction; it has a nanocrystalline structure, a signature of possible recrystallization of this unidentified phase, and a Nd:Fe atomic ratio ranging from 2:3 to 3:2.

The microstructure of the die-upset sample is shown in Fig. 3. It consists of platelike grains, ~ 600 nm in length by 150 nm in width, together with larger equiaxed grains that contain a speckling of precipitates in the grain interior [Fig. 3(a)]. A second phase, similar to that found in the hot-pressed sample, is also observed at the grain junctions in both the platelike and equiaxed regions of this sample. It too possesses a nanocrystalline structure and a Nd-rich composition, with a Nd:Fe ratio up to 3:1, close to that determined by Mishra.^{6,14} Figure 3(b) shows a higher magnification of a platelike region with many of the second-phase pockets. Strong strain contrast is visible around these pockets, which may indicate an incoherent interface between the main 2-14-1 grains and the second-phase grains. The boundaries along the length of the plate-grains are usually free of a grain boundary phase, although it has also been observed that the second phase at the grain junctions in some cases extends into the grain boundaries, but decreases in thickness and eventually diminishes. The exact composition of the materials found in the thin grain boundary region (in the order of

FIG. 2. (a) Grain structure of the hot-pressed sample. The inset shows the EDX spectrum of the 2-14-1 main phase, and (b) high magnification TEM image of a grain boundary junction.

1–2 nm) is in question due to the spreading of the electron beam through both the main-phase grains and the grain boundary phase. EDX spectra show either composition of the main 2-14-1 phase, or of a phase that is rich in Nd compared to the grains.

DISCUSSION

Although the microstructures of the two samples are quite different—the hot-pressed sample has an isotropic structure while the die-upset sample has an anisotropic plate-like grain structure—the grain boundary structure and composition remain rather similar. Information obtained during the course of the study can be divided into two categories: that obtained from meso-scale (10 nm range) features and that obtained from fine-scale (1–3 nm range) features. In general, materials in the thinner grain boundary regions are found to be Fe-rich in the hot-pressed microstructure and remain indeterminate in the die-upset microstructure.

The presence of second phases, in the grains and at the grain boundaries and grain boundary junctions, is thought to be responsible for the reversal mechanisms in these magnetic alloys.^{1–6} The role that these second phases play however is difficult to ascertain because different studies of similar materials have reported different structures and phase constitution. Mishra and his colleagues reported finding of a bcc structure with a lattice parameter close to that of β -Nd,¹⁵ and Nd-rich phases,^{6,14–16} including Nd oxides,¹⁴ in a Nd-rich B-deficient rapidly quenched alloy, while in Nd-rich B-rich alloys, Chu *et al.* reported finding of $\text{Nd}_5\text{Fe}_2\text{B}_6$ grains and amorphous Nd-rich grain boundaries in rapidly quenched

FIG. 3. (a) Grain structure of the die-upset sample showing both platelike and equiaxed grains, and (b) high magnification TEM of the platelike grains showing the strain contrast around the second phase pockets.

samples, and hexagonal structured Nd-rich intragranular precipitates in the hot-pressed samples.¹⁶ Clearly the microstructures and phase constituents are very dependent upon composition and the processing conditions. The effect that these two parameters have upon microstructure, and hence magnetic properties, is not well understood and still is an active area of debate.

In the case of the two related magnets studied here, differences in the magnetic behavior can be explained by microstructural differences, because both the thicker and the thinner intergranular regions were found to have roughly the same composition and structure in both magnets. The grain boundary junctions were observed in both samples, although those in the die-upset sample seem to have a higher Nd:Fe ratio than those in the hot-pressed sample. The higher coercivity in the hot-pressed sample most likely stems from the difficulty in magnetizing randomly oriented grains rather than from the smaller grain size in this case. A finer grain size would be expected to yield a higher coercivity by either (i) reversal by rotation if the particle is too small to sustain a domain wall, or (ii) impedance (pinning) of domain walls by grain boundaries or grain boundary phases. Reversal by rotational processes is unlikely since the grains in the hot-pressed material are not single-domain particles due to magnetostatic and exchange interactions. There is no clear evidence from room-temperature magnetic data for pinning-controlled coercivity; the linear approach to both coercivity and remanence are characteristic of nucleation-controlled

reversal.¹⁷ The poor remanence in the hot-pressed sample is thus due to the approximately random orientation of the grains, and alignment of the grains upon die-upsetting is responsible for the increase in the remanence.

The presence of excess iron in the grain boundary phase has several important consequences with regards to inter-grain interactions. One result is that it is possible that the grains are exchange-coupled as well as magnetostatically coupled by the presence of a ferromagnetic grain boundary phase. The amount of this intergranular phase found in these magnets however is too small (1–2 vol %) to produce an observable enhanced remanence.¹⁸ However it may allow for the existence of lower-anisotropy sites for the nucleation of reverse domains while reducing the probability of domain wall pinning at the intergranular phase.

CONCLUSIONS

Transmission electron microscopy was used to study the microstructure and composition in hot-pressed (MQ-2) and die-upset (MQ-3) $\text{Nd}_2\text{Fe}_{14}\text{B}$ -based magnet alloys. The hot-pressed sample with the nominal composition $\text{Nd}_{13.75}\text{Fe}_{80.25}\text{B}_6$ shows faceted grains of the 2-14-1 phase, while die-upset NdFeB samples having the same bulk composition show platelike grains, together with larger equiaxed grains that contain a speckling of precipitates in the grain interior. The thinner grain boundaries exhibit a Fe-rich composition near that of the NdFe_3 phase, while the thicker intergranular phases are Nd-rich. Nanocrystallites with Nd:Fe ratio near 7:3 are also found at the grain junctions in the equiaxed grain regions of the die-upset samples. The initial magnetic properties of the two samples are different, which is attributed to the difference in the anisotropy of the grain structure. The high coercivity and low remanence of the hot-pressed sample result from the random orientation of the grains. The Fe-rich phase at the grain boundaries in both samples could provide exchange-coupling between the grains and sites for possible reverse magnetization nucleation.

Magnequench, Delphi(E), General Motors Corp., Anderson, Indiana 46013

Magnequench NdFeB powders having high and low rare earth contents were explosively compacted to obtain cylindrical magnets. The magnetic properties were found to be isotropic and were superior to conventionally consolidated isotropic magnets. The $(BH)_{\max}$ was 14.7 MGOe and the remanence was 8.7 kG for the explosively compacted magnet with lower rare earth content. X-ray diffraction patterns confirm the explosively compacted magnet to be crystalline and the predominant phase to be the 2-14-1 phase. Transmission electron microscopy examination showed a microstructure to consist of 20–25 nm size equiaxed grains consistent with the magnetic measurements. © 1996 American Institute of Physics. [S0021-8979(96)38408-5]

I. INTRODUCTION

High $(BH)_{\max}$, use of less strategic Nd, and high concentration of low cost Fe and B have made NdFeB alloys extremely attractive for many high-performance permanent magnet applications.^{1–5} With higher $(BH)_{\max}$, high power levels and high magnetic fields can be obtained using smaller magnets and consequently the use of NdFeB magnets, with $(BH)_{\max}$ in the range of 35–40 MGOe, has resulted in revolutionary developments in the miniaturization of motors, actuators and sensors, and other devices critical to a wide range of industries and technologies.

The Magnequench division of General Motors produces NdFeB magnetic powders by melt spinning ribbons of Nd-Fe-B alloy followed by comminution. These powders are used to make polymer bonded magnets, hot pressed isotropic magnets, and hot deformed anisotropic magnets.^{1–4} The microstructure developed by these processes consists of grains of the hard magnetic phase $\text{Nd}_2\text{Fe}_{14}\text{B}$ separated by a non-magnetic grain boundary phase.^{1,5–7}

Powders can also be consolidated with shock waves in the appropriate pressure range and duration for a given powder.^{8–12} The shock waves may be generated by detonating shaped explosive charge in contact with the powder container or by impact with a high velocity projectile. The pressures in the shock front that moves through the powder are several times the flow stress of the material, typically several GPa. Consolidation occurs by particle deformation followed by extrusion in to the void space. The material near the surface of the particle will see temperature pulses exceeding the melting point over durations that range from microseconds to milliseconds but quickly quenched by heat flow in to the bulk of the powder particle. Thus it is possible to nearly preserve the original microstructures that have been obtained by the rapid solidification processing of the powder. Densities approaching theoretical density can be achieved by a proper choice of pressure and pulse duration. Also effective breakup of adherent oxide film can be achieved minimizing the tendency to fracture along prior particle boundaries.

University of Utah in collaboration with Magnequench is carrying out explosive compaction studies of isotropic and anisotropic powders to obtain full density. This article examines the influence of explosive compaction on the magnetic

properties and microstructures of two isotropic NdFeB powders. The two powders, one containing lower amount of rare earth and the other containing an higher amount of rare earth, are examined. The explosively compacted magnets were characterized using x-ray diffraction, scanning electron microscopy and transmission electron microscopy. The magnetic properties were examined with a vibrating sample magnetometer.

II. EXPERIMENTAL WORK

Two isotropic powders used in this study were MQP-A powder and MQP-B powder. The nominal composition of the MQP-A powder was Fe-30.5 wt % total rare-earth-0.9 wt % B and that of powder MQP-B was Fe-5 wt % Co-27.5 wt % total rare-earth-0.9 wt % B. The rare earth component consisted of mainly Nd with 0.5% (max) of Pr and 0.2 wt % (max) of other rare earths. The powders were packed in a copper tube closed at one end with a tight-fitting steel rod. The open end of copper tube was then sealed with a steel cap. The packed density of the powder was ~55%. The cop-

FIG. 1. Explosive container assembly for explosive compaction of NdFeB powders.

FIG. 2. (a) An explosively compacted NdFeB magnet and (b) micrograph of a cross section of the FeNdB magnet piece shown in (a).

per tube assembly containing the powder was placed centrally in an explosive charge container as shown in Fig. 1. The cylindrical detonator fuse was inserted in the snugly fitting hole in the cap of the PVC container. The liquid-slurry explosive Dyno Nobel 207X was prepared by mixing the two components, perchlorate-base liquid component A and an aluminum-based component B. The mixture was then poured into the container, which was closed with the cap assembly containing the compacted copper tube. The weight of the explosive charge used for the compaction experiments was ~350 g.

Explosive compaction using large amounts of explosive charges as indicated above were performed at the Dyno Nobel facilities just outside of Salt Lake City. The shock wave velocity was measured in several explosive experiments using two triggers placed at different locations of the container. Typical shock wave velocities achieved in these experiments were ~4300 m/s. The detonation velocity is related to the compaction pressure by the following relation,¹³

$$DP = 2.325 \times 10^{-7} \rho (VOD)^2,$$

where VOD is the velocity of detonation in ft/s, DP is the detonation pressure in kbar, and ρ is the density of the explosive mix in g/cc. The resulting compaction pressure was ~6 GPa. The explosively compacted specimens prepared from MQP-A powder and MQP-B powder are hereafter referred to as EC-A and EC-B, respectively.

Optical microscopy and scanning electron microscopy techniques were used to examine the porosity and crack size distribution in EC-A and EC-B specimens. The microstructure was examined by transmission electron microscopy (TEM) using a Jeol 2000 FX II STEM. X-ray diffraction was performed using a Siemens D5000 diffractometer. Differential thermal analysis was carried out using a Perkin Elmer DTA⁻⁷ system. Specimens 4.5 mm×4.5 mm×4.5 mm in size were used for the magnetic measurements using a vibrating-sample magnetometer (VSM).

III. RESULTS AND DISCUSSION

Figure 2(a) shows an optical micrograph of one of the explosively compacted piece and Fig. 2(b) shows a cross section of the compacted piece. The sample shows in general excellent compaction with some cracking. A central hole is

FIG. 3. X-ray diffraction pattern of explosively compacted EC-B magnet.

observed along the axis of the cylindrical piece and this arises from the melting and ejection of material under the focussed energy of the shock waves near the center. The hole is called the Mach stem and results from an excessive consolidation pressure.⁹ The size of the hole was observed to decrease in the direction of shock wave propagation and was not observed in over a 5 mm length at the other end. This hole can be eliminated by lowering the detonation pressure or by having an additional copper tube sleeve surrounding the tube that contains the powder.^{10,14} The cracks observed arise from the tensile component of the reflected shock waves. These can be minimized or eliminated by controlling the ratio of the explosive charge to the powder, the detonation pressure and the use of a two tube design as mentioned earlier. No significant variation in the porosity distribution

FIG. 4. Demagnetization curves for three orthogonal directions in EC-B magnet.

TABLE I. Magnetic properties of EC-A and EC-B magnet.

Specimen orientation	M_s (kG)	B_r (kG)	H_{ci} (kOe)	BH_{max} (MGOe)
EC-A magnet				
z-direction	8.6	7.63	14.57	11.41
x-direction	7.94	7.51	14.51	11.03
y-direction	8.00	7.59	14.46	11.53
EC-B magnet				
z-direction	8.96	8.54	9.41	14.05
x-direction	9.11	8.72	9.47	14.72
y-direction	9.02	8.64	9.17	14.58

and cracking was observed along the length of the compact. The density of specimen EC-A was 7.2 g/cc while the density of EC-B was 7.3 g/cc.

Figure 3 shows an x-ray diffraction pattern obtained for explosively compacted MQP-B powder. The peaks observed correspond to 2-14-1 phase. This confirms that the material is still crystalline and contains predominantly the hard 2-14-1 phase. The amount of other possible phases was small and could not be identified from this pattern. The differential thermal analysis of the compacts revealed a major peak at 1172 °C, corresponding to the melting of the 2-14-1 phase.

Demagnetization curves determined using a VSM in three orthogonal directions showed that the magnetic properties were isotropic in both EC-A and EC-B magnets. Figure 4 shows the demagnetization curves for EC-B magnet. Table I summarizes the values of B_r , H_{ci} , and BH_{max} for the two specimens obtained from the demagnetization curve which shows essentially no difference in magnetic properties measured along the three orthogonal directions. This is expected as the explosive compaction occurs under nearly isotropic compressive pressure conditions and the microstructure of the ribbons are nearly preserved. In Table II, the magnetic properties of bonded isotropic magnets, and hot pressed magnets are compared with the explosively compacted magnets. The BH_{max} values observed are higher and comparable to hot pressed magnets.^{3,4} The densities observed in the present EC-A and EC-B specimens are ~95%. The explosive compaction could achieve nearly 100% density

FIG. 5. A TEM micrograph of an EC-B specimen.

and hence a >10% increase in BH_{max} is possible by this processing route which makes this approach very attractive.

Figure 5 shows a TEM image of an EC-B specimen. The microstructure consists of equiaxed grains on the order of 20–25 nm. This microstructure is similar to that observed in the original ribbon. The equiaxed microstructure observed is consistent with the isotropic properties observed for specimens EC-A and EC-B. It is very important to note that the explosive compaction has preserved the rapidly solidified ribbon microstructure and therefore do not have any adverse effects of grain growth. Further TEM work is in progress to understand the enhancement in magnetic properties by explosive compaction.

ACKNOWLEDGMENTS

The support of this work by GM-Magnequench and Dyno Nobel through the provision of materials, experimental facilities, and personnel for the explosive compaction experiments is gratefully acknowledged.

The protective coatings of NdFeB magnets by Al and Al(Fe)

C-D. Qin, A. S. K. Li, and D. H. L. Ng

Department of Physics, The Chinese University of Hong Kong, Shatin, Hong Kong

NdFeB permanent magnets are coated by two different methods, dip coating and evaporation coating, with Al. It is found that an intermetallic reaction has occurred and formed a dominant phase of $\text{FeAl}_{2.5}\text{B}_x$ at the interface between the Al coating and the magnet material. Such reaction enhances strong bonding between the coating and the magnet. When Al(Fe) is used for the coating, no detectable intermetallic phase is observed, and therefore the amount of magnet material is conserved. We have studied the effect of the intermetallic phase on corrosion protection of the magnet. It is found that this phase is less resistive towards HNO_3 solution than pure Al; but it is more resistive towards NaOH and NaCl. The investigation of the changes of microstructures of the coatings under different tempering conditions have also been carried out. The results show that the heat treatment at 500 °C for 10 min for a $\sim 2 \mu\text{m}$ thick Al coating by evaporation can produce an optimal layer of intermetallics. If the temperature is too low, the coating will not adhere to the magnet or if too high, it will fully react with the magnet and produce a rough coating surface.

© 1996 American Institute of Physics. [S0021-8979(96)38508-1]

I. INTRODUCTION

It is well known that NdFeB type permanent hard magnets possess excellent magnetic properties. However, their large scale commercial applications are hindered partly by their poor corrosion resistance.¹ To improve the corrosion resistance of the magnets, methods such as doping^{2,3} and surface coatings by plastic resin, Al or Ni have been employed.^{4,5} Whereas the previous works have demonstrated the effectiveness of various coatings under corrosion tests, the microstructure and chemical interaction between the coatings and the magnetic materials have not been fully studied. To carry out further study on the mechanisms of the metallic coatings for corrosion protection of the magnets, we have the NdFeB magnets coated by two different methods, dip coating and evaporation coating, with either Al or Al(Fe) alloy. The interfacial reactions are studied and the intermetallic compounds have been identified. The effect of the various coatings under different processing conditions are evaluated against different corrosion tests.

II. EXPERIMENTAL PROCEDURES

Commercial $\text{Nd}_{15}\text{Fe}_{77}\text{B}_8$ cast ingot was cut into 3 mm \times 3 mm \times 8 mm blocks. The large surface of each block was polished. These blocks were then coated by two different techniques. In the dip coating method, the sample was dipped either into molten Al or molten Al(3wt%Fe) up to 60 sec at 750 °C. In the evaporation method, the blocks were placed in a vacuum of 3×10^{-5} mbar with vaporized Al. The coated samples were then treated with different tempering conditions in a vacuum of 5×10^{-5} mbar in order to find a suitable tempering condition to produce strong bonding between the coating and the magnet. The final products were cut, polished and tested with different corrosive solutions such as HNO_3 , $\text{HCl} + 10\text{H}_2\text{O}$, and NaCl and NaOH saturated solution at room temperature. In order to examine the rates of corrosion of the outer layer of Al, the intermetallic phases and the magnetic matrix, we have used a dip coated magnet with relatively thick Al and intermetallic layers (~ 0.5 mm each) as a result of being heat treated for 30

min at 600 °C for the corrosion test. The sample was corroded in the NaCl+NaOH saturated solution, and its weight was continuously measured by a thermogravimetric analyzer so that the rate of corrosion (which is proportional to the rate of weight loss) can be deduced. Scanning electron microscopy (SEM) and electron probe microanalysis (EPMA) were also employed in this study.

III. RESULTS AND DISCUSSION

A. Heat treatment and microstructures

1. Evaporation coated samples

The evaporation coated magnet with Al is smooth and reflective as a mirror. The coating has a thickness of $\sim 2 \mu\text{m}$. When the coated sample is heat treated at 300 °C for 10 min, the Al coating will fall off from the magnet material. One of the possible reasons is because of the differences between the coefficients of thermal expansion of Al and the NdFeB magnet. When the temperature of sample is changed, thermal stresses will build up and destroy the weak interfacial bonding. From the SEM inspections of the fallen Al layer and the magnet substrate, there is no trace of interfacial reaction product. This indicates that the heat treatment of such temperature cannot induce any intermetallic reactions. When a heat treatment at 400 °C was used, the debonding of the Al layer did not occur even though no intermetallic layer was observed as shown in Fig. 1. However, the bonding is weak as indicated by the presence of a groove at the interface. At or above 500 °C, the heat treatment produces an intact magnet coated with Al. Here, we observed that there are intermetallic phases between the coating and the magnet as an evidence to the occurrence of the interfacial reactions. Figures 2(a) and 2(b) show from the top of the evaporation coated Al magnets after the heat treatments of 500 °C and 600 °C for 10 min, respectively. In the former, the intermetallic reaction has not consumed all the Al of the coating. However, the Nd segregated at the grain boundaries of the magnet, is particularly high, has reacted actively with the Al coatings, and the product of the reaction pushed its way up to

FIG. 1. A cross-sectional view shows no observable intermetallic layer between the Al coating (indicated with mark Al) and the NdFeB magnet (on the right).

the surface and appears as the grain boundary-like pattern as seen in Fig. 2(a). It was determined this intermetallic reaction product to be $\text{Nd}_{23\pm3}\text{Fe}_{4.5\pm0.4}\text{Al}_{73\pm3}$ while the composition of the adjacent Al coating was $\text{Nd}_{3\pm0.1}\text{Fe}_{18\pm1}\text{Al}_{79\pm1}$. The high content of Fe up to 18 at.% found in the Al coating suggested that the solubility of Fe in Al is enhanced by the presence of Nd. For the heat treatment of 600 °C, most of the Al coating is consumed in the intermetallic reaction, thus the surface of the magnet shows the white intermetallic phase as shown in Fig. 2(b). Its composition is found to be $\text{Nd}_{4\pm0.5}\text{Fe}_{27.5\pm0.5}\text{Al}_{68\pm0.5}$, or $\text{FeAl}_{2.5}$ for simplicity (the composition of boron cannot be determined by EPMA). On the

FIG. 2. Two top views of the evaporation coated Al magnet after the heat treatment of 500 °C and 600 °C for 10 min respectively. (a) The bright area are the intermetallic product from the reaction of the Al layer and the Nd segregated at the grain boundary of the magnet. (b) Most of the Al has been reacted with the Nd of the magnet and therefore the coating surface is converted to rough intermetallic phases. Some pieces of Al coating still remain and appear as dark patches.

FIG. 3. (a) and (b) are the cross-sections of dip coated samples in Al and Al(3wt%Fe), respectively. The magnet is in bright contrast while the Al and Al(Fe) are in dark contrast.

magnet surface, however, there exist some pieces of reacted Al coating (appears dark in the picture) which have the composition of $\text{Nd}_{3\pm0.3}\text{Fe}_{20\pm1}\text{Al}_{77\pm1.5}$, and are similar to those found in the surface of the 500 °C heat treated samples. This highly reacted coating is not suitable for corrosion protection because its surface is rough and not uniform.

2. Dip coated sample

For the dip coated magnet by molten Al at 750 °C for 30 s, the intermetallic reaction product is $\text{Nd}_{3\pm2}\text{Fe}_{28\pm1}\text{Al}_{69.7\pm1}$, or $\text{FeAl}_{2.5}$ for simplicity.⁶ As the intermetallic reactions involve an extensive amount of Fe, it is expected that the use of Al(Fe) alloy for coating will reduce the consumption of Fe from the NdFeB magnet, thus the content of the magnet elements can be preserved. To show the different intermetallic reactions for the two coating materials, Al and Al(3wt%Fe), the coating procedures were performed in identical furnace conditions at 750 °C for 1 min. Figure 3(a) shows that an intermetallic phase of $\sim 92 \mu\text{m}$ thick has been formed for Al coating, while Fig. 3(b) shows no obvious intermetallic phase at the interface of the coating and the magnet for the magnet coated by Al(Fe). Nevertheless, both figures show that there is no groove at the interface. However, it is possible that some extent of intermetallic reactions did occur at the interface in the Al(Fe) coated magnet, but has not been resolved by the SEM. Such a result thus shows that Al alloyed with Fe can significantly reduce the consumption of magnet materials. It is recommended that Al

alloyed with Fe should be used for the coating of NdFeB type magnets; or at least it should be used as an intermediate coating layer for Al coating to the magnets.

B. Corrosion tests of the dip coated magnets

When the dip coated magnet is tested in the $\text{HNO}_3 + 4\text{H}_2\text{O}$ solution, the intermetallic phase appears very stable even after the magnet itself has been fully dissolved by the acid. This shows that such a coating of Fe-Al intermetallic phases can be used for corrosion protection. However, we also find that Al itself is more corrosion resistant to acid dissolution than the Fe-Al phases. Thus, in protecting the NdFeB magnets in the HNO_3 environment Al coating is much more appropriate. In the corrosion test using $\text{HCl} + 10\text{H}_2\text{O}$, it is found that the corrosion resistance is in the order of: intermetallic phases > Al > magnet, this is assessed by measuring the relative thickness of each material being dissolved. The results thus suggest that thicker intermetallic phases, produced by higher temperature and longer tempering time of Al coated magnet, is an advantage for the NdFeB magnet being used in the HCl type acidic environment. When the dip coated magnet is tested in the saturated NaOH and NaCl solution, the results show that the corrosion resistance is in the order of: magnet > intermetallic phases > Al. Their rates of weight loss measured by the thermogravimeter are 2.5, 12.7 and 17.3 g/cm²/min, respectively. Therefore, in the NaOH and NaCl environment, the magnet should be coated with extra thick Al.

IV. CONCLUSIONS

In this paper, we have reported that both evaporation coated and dip coated Al are suitable for the corrosion pro-

TECTIVE COATINGS FOR THE NdFeB MAGNETS. It is found that intermetallic reactions at the interface of the coating and the magnet are essential for the firm adhesion of Al layer to the NdFeB magnet materials. The minimum temperature required for the occurrence of a significant intermetallic reaction is around 500 °C for the evaporation coated Al. The intermetallic phases are mainly $\text{FeAl}_{2.5}$ based for both evaporation and dip coated coatings. When the magnet is dip coated by Al, large scale intermetallic reaction occurs. As the Al(3wt%Fe) is used for the coating, it is found that there is no observable intermetallic reaction, and the magnet materials have not been disturbed. The corrosion tests show that in HNO_3 solution the order of corrosion resistance is: Al > intermetallic phase > magnet, while in HCl solution it is: intermetallic phase > Al > magnet, and in NaOH+NaCl saturated solution it is: magnet > intermetallic phase > Al.

Twin screw extrusion of a metal particle dispersion

H. Göktürk^{a)} and K. Maki

Kao Corporation, Recording and Imaging Science Laboratory, 2606, Akabane, Ichikaimachi, Haga, Tochigi, 321-34, Japan

Twin screw extruder is employed as a mechanical dispersion tool in the processing of particulate media incorporating high specific surface area (SSA) pigments. In this study, the effectiveness of a typical screw configuration used in the processing of formulations containing acicular iron particles of SSA=50 m²/g was experimentally investigated. During a steady state mixing operation, the extruder was brought to a dead stop, the screws were pulled out and material samples were collected from nine different screw sections. These samples were analyzed to determine the progress of the mixing process as the dispersion flows from section to section. Using SEM micrographs of the material samples, magnetic particle distributions corresponding to different screw sections were identified. The microstructure was observed to change from a granular appearance of aggregates and voids to a coagulated but relatively more uniform distribution of magnetic particles. The state of the dispersion was also magnetically evaluated by probing the magnetostatic interaction in the dispersion samples. Both hysteresis curves and remanence curves of the samples were utilized for this purpose. Interaction parameters associated with the hysteresis curves, such as coercivity, did not exhibit clear trends from section to section. The remanence curves were found to be more appropriate to analyze the state of the dispersion. Peak ΔM values calculated from the remanence curves followed the changes that were observed in the microstructure. It was concluded from the overall results that the extrusion process could be further improved by changes in the screw configuration. © 1996 American Institute of Physics. [S0021-8979(96)80408-1]

INTRODUCTION

Particulate recording media consist of magnetic particles dispersed in a polymeric binder. Magnetic particles commonly available are gamma iron oxide, cobalt doped iron oxide, chromium oxide, barium ferrite, or metal (mainly iron) powders.¹⁻³ During the course of development of the particulate media, there has been a shift from iron oxides towards metal particles which are more attractive because of their higher coercivities and higher magnetizations. For example, digital audio tape, one of the newest tape products, employs metal particles. This trend from iron oxides to metal particles has necessitated concomitant improvements in the dispersion preparation methods because metal particles are smaller in size, they have higher specific surface areas and they are more difficult to disperse. One of these improvements is the introduction of a mechanical dispersion method by means of a twin screw extruder.⁴ Metal particle dispersion containing a high loading level of the solids is kneaded by the extruder. High shear force deformations generated within the extruder are believed to help break up the aggregates. The motivation of this study is to analyze the twin screw kneading process to understand the dispersive mixing brought about by the extruder and to investigate improvements that can be implemented for pigments presenting greater difficulty of dispersion. Such pigments are considered for the purpose of increasing the recording densities further.^{2,5}

MATERIALS AND PROCESSING

The magnetic dispersion used in the study was prepared by using acicular iron particles of length: 180 nm, diameter: 20 nm, specific surface area: 50 m²/g, and saturation magnetization: 125 emu/g. Carbon black and alumina were also included in the dispersion in small amounts. The binder consisted of a combination of polyvinyl chloride and urethane polyester polymers. The polymers were dissolved in a solvent mixture which included cyclohexanone, toluene, and methyl ethyl ketone. The solids content of the dispersion was 80% by weight and the pigment to polymer ratio was about 5.

The operation of the twin screw extruder involves the selection of a number of parameters including the screw configuration, the rotation rate of the screws, the flow rate of the material, and the process temperatures of different zones. The screw configuration, being the most important parameter in the functioning of the extruder, was chosen as the main subject of the analysis. As the material flows from one section of the extruder into the next, it goes through changes in

FIG. 1. Scaled schematic view of the screw configuration; screw sections consisting of kneading disks are marked as K and the angle of stagger of the disks is indicated.

FIG. 2. Examples of (a) regular and (b) kneading screw sections.

terms of the distribution of the ingredients. The objective of the analysis is to understand the effect of different kneading sections on the state of the dispersion.

During a kneading run, the extruder was brought to a dead stop after reaching steady state operation, the screws were pulled out and material samples were collected from nine different kneading sections. Samples of the extrudate (labeled as 10 in Fig. 1) were also included in the study. All the samples were analyzed in terms of their microstructure and macroscopic properties to evaluate the state of the dispersion. The volatiles within the material samples, unavoidably, evaporated during the sample collection, therefore the solids content of the analyzed samples were all the same although the distributions of the constituents were different.

MICROSCOPIC CHARACTERIZATION

The microstructure analysis of the material samples collected from the extruder was based on scanning electron micrographs (SEM) obtained by using a Hitachi SEM, model S-4000. Figure 3(a) shows a sample micrograph of material samples from kneading section 1. The material has a granular appearance consisting of particles and voids. Some of the particles are clumped together in aggregates; individual particles are also observable. Comparison of the microstructure of the samples from kneading section 1 [Fig. 3(a)] with that of kneading section 5 shown in Fig. 3(b) indicates that they have similar features. Microstructure of samples from kneading sections 2 to 4 (not shown) also look like those from kneading sections 1 and 5. These kneading sections occupy a considerable portion of the screw length, yet, the micrographs do not suggest a noticeable change occurring in the microstructure of the dispersion during dry kneading.

A micrograph of the material samples from kneading section 7 is shown in Fig. 3(c). The microstructure is distinctly different from those of sections 1 to 5. The voids seem to disappear, the magnetic particles tend to a coagulated state and their spatial distribution becomes more homogenous. The micrographs of the samples from kneading sections 8 and 9 (not shown) are very similar to that of kneading section 7. The introduction of the solvent into the dispersion between kneading sections 6 and 7 seems to cause a significant change in the microstructure of the material. Section 6 is behind the solvent port, but the material in section 6 also gets affected by the solvent pumped into the extruder.

FIG. 3. Micrographs of material samples from kneading sections (a) 1, (b) 5, and (c) 7.

Cutaway views of the material samples, exposed by cutting the samples with the knife accessory of the SEM, were also obtained to see the internal structure. The micrographs of the cutaway sections show that the distribution of the solvent within the dispersion is not uniform in section 7 as indicated by a lack of coagulation in some parts. The solvent distribution improves in sections 8 and 9.

MAGNETIC MEASUREMENTS

Evaluation of the state of the dispersion from a magnetic point of view is very desirable since the dispersion of the study is intended for a magnetic function. The approach that is selected in this study is based on the magnetostatic interaction that exist between the particles of the dispersion. The magnetostatic interaction is inversely related to the separation between the magnetic particles. It is expected that during the kneading process the average inter particle distance would change due to attrition of the aggregates and spatial rearrangements of the particles. Variations in the inter particle spacing would give rise to changes in the intensity of particle interactions. By measuring magnetic parameters which are influenced by inter particle interactions in a well known manner, one can assess the state of the dispersion.

The experimental investigation of magnetic inter particle interactions was performed by measuring the hysteresis and remanence curves of the material samples collected from dif-

FIG. 4. Variation of the coercivity and the switching field distribution SFD as a function of the kneading section; six samples per data point.

FIG. 5. Variation of the peak ΔM values as a function of the kneading section; six samples per data point.

ferent kneading sections by means of a vibrating sample magnetometer, model BHV55 made by Riken Denshi Company of Japan. The material samples from the kneading sections were irregular shapes of solid like texture owing to their relatively high solids content. It was necessary to shape the material in order to ensure that samples placed in the uniform magnetic field of the VSM would also have uniform fields inside. It is known from analytical studies that ellipsoidal shapes satisfy this requirement well. Therefore the samples for magnetic measurements were prepared, by cutting and filing, as low aspect ratio (<10) ellipsoids.

The parameters chosen from the hysteresis curves to understand the intensity of particle interactions included coercivity H_c and switching field distribution SFD. The variation of these parameters with the intensity of inter particle interactions had been studied extensively.^{1,3,8,9} For randomly oriented acicular particles, increasing intensity of particle interactions decrease coercivity and broaden SFD. The chosen parameters are plotted in Fig. 4 as a function of the kneading section. The error bars shown in all of the figures represent 95% confidence intervals of the Student's t -Distribution. The hysteresis curve parameters exhibit weak trends from section to section. For example the average coercivity increases about 3% from section 1 to 6 then decreases by the same amount up to section 9. The average SFD values are about the same from sections 1 through 7, whereas, those of sections 8 to 10 have about 10% higher values. Higher SFD values imply increased intensity of inter particle interactions due to smaller inter particle spacing. The size of the error bars generally conceal the trends, but it is clear that sections 6 and 7, where the solvent is introduced, serve as a demarcation point.

Inter particle interactions can be also investigated from remanence curves.^{3,9,10} The isothermal remanence and the demagnetization remanence curves of the material samples were measured and the ΔM function was calculated from these curves. For randomly oriented acicular particles ΔM is a negative, bell shaped curve with a single maximum. Since ΔM function shows the degree of deviation of the dispersion from the hypothetical case of non interacting particles, the peak value of ΔM was selected as an interaction parameter. The measured peak ΔM values of the material samples are plotted in Fig. 5 as a function of the kneading section. The following information can be deduced from the data: Peak ΔM values pertaining to kneading sections 1 to 5 are very nearly equal. This result confirms the observation that changes in the microstructure of material samples from these sections are not noticeable. Peak ΔM values of kneading sections affected by the solvent addition, i.e., sections 6 to 9, increase regularly. The increase in the intensity of interactions can be anticipated from the coagulation observed in the micrographs. Peak value of ΔM serves as an indicator of the degree of coagulation, which is difficult to quantify from the micrographs. The increase in the peak ΔM values does not level off towards the end of the extruder. The change in peak ΔM from kneading section 7 to 8 and 8 to 9 are about equal. Likewise, the size of the error bars are about the same in sections 7, 8, and 9. These results suggest that the mixing performed after the solvent addition might be incomplete.

Preparation of acicular iron nanoparticles by the reduction of ferrous salt in the presence of tubular lecithin assemblies

Jason L. Cain and David E. Nikles

Department of Chemistry and Center for Materials for Information Technology, University of Alabama, Tuscaloosa, Alabama 35487-0336

Ferromagnetic α -Fe particles were prepared by reduction of Fe^{2+} in the presence of tubular lecithin assemblies found in lecithin/cyclohexane/water association colloids. The particles consisted of both large single- and multi-domain acicular rods, 0.25–5 μm in length with a length to width ratio of at least 6:1, encapsulated in lecithin. The coercivity depended on the reaction medium and ranged from 7 to 131 Oe. The highest coercivity particles were obtained in the cyclohexane-rich region of the ternary phase diagram. © 1996 American Institute of Physics. [S0021-8979(96)07108-3]

INTRODUCTION

There are many reports of the preparation of nanometer size magnetic particles formed in reverse micelles. Magnetite particles were prepared by precipitation of mixtures of FeCl_2 and FeCl_3 in aerosol OT (AOT)/water/isooctane¹ or AOT/water/cyclohexane² microemulsions. Barium ferrite nanoparticles were prepared by coprecipitation of precursor carbonates in cetyltrimethylammonium bromide (CTAB)/water/butanol/octane microemulsions, followed by calcining.³ Cobalt⁴ or iron⁵ nanoparticles were prepared by sodium borohydride reduction of Co^{2+} or Fe^{2+} solubilized in AOT/water/hydrocarbon microemulsions.

Our objective is to prepare acicular iron particles with a particle size of 50 nm and a coercivity of greater than 2000 Oe. The approach is to use association colloids as templates to control the size and shape of iron particles formed in their presence. Reverse micelles are mixtures of surfactant, oil, and water where a monolayer of surfactant separates the water from the oil. Of the many ternary systems that have been shown to form reverse micelles, the one of most interest to this work is the lecithin/cyclohexane/water system, Fig. 1.^{6,7} When water is added to hydrocarbon solutions of soybean lecithin until the value of w (the molar ratio of water to surfactant) exceeds 1, there is a huge increase in solution

viscosity.⁸ Light scattering and neutron diffraction experiments have shown that the lecithin forms long, flexible tubes with an aspect (length to diameter) ratio approaching 100.⁹ We have reported that reduction of Fe^{2+} in these tubes led to chains of spherical α -Fe particles trapped in the tubular assemblies.¹⁰ Here we report our attempts to control the reduction process in order to prepare acicular iron particles.

EXPERIMENT

Soybean lecithin (purified grade, Fisher Scientific) was dissolved in cyclohexane (HPLC grade, Fisher Scientific) by stirring for 12 h. The next day a 0.15 M solution of ferrous chloride in water was added to the lecithin/cyclohexane solution. The volume of solution was selected to control the composition of water in the colloid. This mixture was allowed to stir vigorously for 15 min, then gently for 3 h, to assure the solution was completely mixed. The solution was allowed to equilibrate for two days after stirring. Over the two day period the mixture separated into two phases. The upper phase, yellow and transparent, consisted of cyclohexane and lecithin, and was discarded. The viscous, turbid,

FIG. 2. Acicular iron particles made in trial 5.

FIG. 4. Acicular iron particles made in trial 3.

lower phase was used for reduction experiments. Sodium borohydride was added to the lower phase in the presence of an applied magnetic field of 1200 G, whereupon a black precipitate immediately formed. The supernatant liquid was decanted from the particles and the particles were rinsed three times with cyclohexane, then twice with ethanol. The particles were dried in an oven under ambient atmosphere at 125 °C overnight. Residual lecithin coated the particles and somewhat protected them from air oxidation. This allowed a day or so to obtain structural or magnetic data, before the particles corroded. After drying, the particles were characterized by vibrating sample magnetometry, x-ray diffraction, and transmission electron microscopy.

RESULTS AND DISCUSSION

Reduction of Fe^{2+} in lecithin/cyclohexane/water ternary systems gave iron particles that were either superparamagnetic or ferromagnetic, depending on the reaction conditions. X-ray diffraction showed only one peak: the $\alpha\text{-Fe}$ (110) reflection at $d=202.7$ pm. The data in Table I shows the effect of reaction conditions on the magnetic properties of the iron particles. Trials 4 and 5 gave ferromagnetic hysteresis loops, while the other trials gave loops that showed superpara-

magnetic and ferromagnetic components. Transmission electron micrographs, Figs. 2–4, show the structures of the resulting iron particles. Figures 2 and 3 show micrographs of the highest coercivity iron particles prepared in trial 5. These were large acicular structures with diameters from 150 to 800 nm and length to width ratios of at least 10:1. Particles generated from trial 3, Fig. 4, were large, acicular, multi-domain iron structures and agglomerates surrounded by tubular lecithin assemblies. These lecithin tubules had diameters of approximately 100 nm, with micrometer lengths. These structures were commonly found for the samples having a high superparamagnetic fraction. Most trials yielded particle structures very similar to those found in trial 3.

We were surprised that the reduction in a magnetic field led to acicular iron particles. This result was in contrast to our earlier report¹⁰ of the formulation of chains of iron spheres by the same procedure, in the absence of a magnetic field. There has been a report of high coercivity Fe/Co alloy particles formed by borohydride reduction in aqueous solutions in the presence of a magnetic field;¹¹ those particles consisted of chains of spheres. In all our trials there was a significant fraction of spherical iron particles, not shown in the TEM photographs. The presence of the spherical particles indicates that we do not have adequate control of the particle formation. Future work will be directed at achieving control of the process, so that we can prepare acicular particles with a 50 nm size.

Iron particle surface chemistry and corrosion protection by amine-quinone polyurethanes

Antony P. Chacko and David E. Nikles

Department of Chemistry and Center for Materials for Information Technology, The University of Alabama, Tuscaloosa, Alabama 35487-0336

The ability of amine-quinone polyurethanes to protect iron particles from corrosion was shown to depend on the polymer composition and on the particle surface chemistry. The amine-quinone polyurethanes were prepared from 2,5-bis(*N*-2-hydroxyethyl-*N*-methylamino)-1,4-benzoquinone (AQM-1), tolylene diisocyanate and polytetrahydrofuran diol (average molecular weight 650). The AQM-1 content was varied from 20 to 40 wt % (AQPU-15); the polymer with 40 wt % AQM-1 had the highest affinity for the iron surface and showed the best corrosion protection. AQPU-15 had a higher affinity for the commercial iron particle having a aluminum-rich surface, than for a commercial particle having a silicon-rich surface. Tape samples containing AQPU-15 and the particles having the Al-rich surface showed excellent corrosion resistance, maintaining 98% of the initial saturation magnetization after 48 h exposure to pH 2 aqueous buffer. Samples containing AQPU-15 and the particles having the Si-rich surface completely corroded after 2 h exposure. The presence of aluminum on the iron surface served to enhance the adsorption of AQPU-15 and improve the corrosion resistance. © 1996 American Institute of Physics. [S0021-8979(96)07208-X]

INTRODUCTION

Organic coatings protect metals from corroding through interposition of a continuous, adherent, high resistance film between the metal surface and its environment, to achieve a mechanical exclusion of the environment from the metal surface. However this mechanical exclusion is never achieved practically since all continuous organic films are permeable to some degree to moisture and many coatings have occasional physical defects or acquire them in service. Another practical way of corrosion protection is by the use of corrosion inhibitors.¹ Organic compounds such as amines, acetylenic alcohols, and heterocyclic compounds have been used as inhibitors for industrial applications. The corrosion inhibition efficiency of an organic compound is mostly dependent on its adsorption onto the metal surface. This adsorption involves replacement of moisture by the organic inhibitor at the interface between coating and metal surface. The adsorption of these organic compounds is influenced by the presence of functional groups such as =NH, -N=N-, -CHO, R-OH and R=R in the inhibitor molecule.² Slavcheva *et al.*³ found a definite relation between protective action and the variation of the chemical structure in a given reaction series. For effective corrosion protection, these compounds should

- (i) be polymeric,
- (ii) form a compact barrier film,
- (iii) chemisorb onto metal surfaces, and
- (iv) have high adsorption energy on the surface.²

The discovery of the excellent adhesion of quinone amine polymers to iron surfaces and the further demonstration of their corrosion protection have been reported by Erhan and coworkers.⁴⁻⁶ Muralidhran *et al.* investigated in detail recently the corrosion inhibiting property of an amine quinone oligomer ($M_n=1150$) made by electropolymerization.^{7,8} They demonstrated the corrosion inhibition of iron and steel by these polymers. We have demonstrated that

polyurethane binders containing a 2,5-diamino-1,4-benzoquinone functional group in the polymer chain, amine-quinone polymers, inhibit the corrosion of commercial iron particles.⁹ In this study amine-quinone polymers were further evaluated for their corrosion protection properties. The influence of polymer structure and metal particle surface chemistry on corrosion protection was investigated in an ongoing effort to understand the corrosion protection mechanism of metal particles by amine-quinone polymers.

EXPERIMENT

Three different amine-quinone polymers were prepared by melt polymerization of the three monomers 2,5-bis(*N*-2-hydroxyethyl-*N*-methylamino)-1,4-benzoquinone (AQM-1), tolylene diisocyanate (TDI), and polytetrahydrofuran diol (Terathane® 650, average molecular weight 650). The polymers differed by the AQM-1 content; AQPU-13 contained 20 wt % percent, AQPU-15 contained 40 wt %, while AQPU-16 contained 30 wt %. Details of the polymer synthesis and physical properties were reported earlier.¹⁰ Two different commercial polyvinylchloride wetting binders, PVC-1 and PVC-2, were used for comparison. Commercial iron particles from two different vendors, MP-1 (specific surface area 54 m²/g, H_c 1500 Oe, and σ_s 122 emu/g) and MP-2 (specific surface area 48 m²/g, H_c 2000 Oe, and σ_s 145 emu/g), were obtained. Electron microprobe analysis showed MP-1 to contain 96% Fe, 3.7% Al and 0.2% Si. MP-2 had 80% Fe, 12.8% Co, 2.9% Ni, and 3.8% Si. The microprobe was not sensitive to the oxygen in the particles and the reported composition does not include the oxygen content.

The adsorption behavior of the amine-quinone polyurethanes onto metal particles was studied by exposing the metal particles to solutions of the polymers in tetrahydrofuran (THF) for a period of seven days with continuous agitation. After seven days, the dispersion of metal particles in polymer solution was allowed settle for a day, the superna-

FIG. 1. Adsorption isotherms for amine-quinone polymer adsorption from THF solution onto commercial iron particles, MP-1.

tant solution decanted from the particles, the solution filtered through a 2.0 μm pore size filter to remove any suspended particles. The concentration of polymer remaining in the supernatant solution was determined by spectrophotometry. The amount of polymer adsorbed onto the iron particles was calculated from the initial volume and concentration of the polymer solution and the concentration of the supernatant solution.

MP samples were prepared by dispersing the iron particles in a cyclohexanone solution of a polymer, either an amine-quinone polymer or a polyvinylchloride. The dispersions were cast onto polyester base films using a hand draw-down apparatus that longitudinally oriented the particles. The coatings were dried in a convection oven at 60 $^{\circ}\text{C}$ overnight. The MP tape samples were exposed to pH 2.00 aqueous buffer (sulfamic acid/potassium phthalate buffer) or to 80 $^{\circ}\text{C}$ and 80% relative humidity in a Tenney Th Jr. temperature/humidity chamber. The samples consisted of 6-mm-diameter circles punched from the hand-drawn coatings. They were exposed for a period of time, the saturation magnetization determined by vibrating sample magnetometry (14 kOe saturation field), and then returned for more exposure.

RESULTS AND DISCUSSION

The amine-quinone polymers have a two-phase microstructure consisting of a discrete, crystalline hard segment phase in a continuous, amorphous soft segment phase.¹¹ The amine-quinone monomer is in the hard segment phase and the degree of phase segregation increases with increasing AQM-1 and content. Our model for corrosion protection of iron particles by amine-quinone polymers is the strong adsorption of the amine-quinone functional group to the particle surface. This leads to a crystallization of the hard segment around the particle surface, providing a crystalline barrier against diffusion of oxygen and moisture to the surface.

The AQM-1 content in the amine-quinone polymers has an influence on the adsorption behavior of the polymers to the iron particles, MP-1. The adsorption isotherms, Fig. 1, show that AQPU-13 and AQPU-16 had a similar adsorption

TABLE I. Langmuir parameters for adsorption of amine-quinone polyurethanes onto MP-1 iron particles from THF solution.

Polymer	AQM-1 content	Capacity (A)	Affinity (B)
AQPU-13	20%	140 \pm 2	2.59 \pm 0.23
AQPU-15	40%	158 \pm 3	2.91 \pm 0.31
AQPU-16	30%	142 \pm 3	3.00 \pm 0.40

behavior, while AQPU-15 had an increased adsorption capacity. The isotherms obeyed the Langmuir model, Eq. (1), and fits of the equation to the data gave the Langmuir parameters of capacity (A) and affinity

$$\theta = A \frac{BC}{1 + BC} \quad (1)$$

(B) in Table I. The Langmuir affinity for the three polymers were similar, however the Langmuir capacity was highest for AQPU-15. Repeated attempts to measure adsorption isotherms for adsorption of the commercial polyvinyl chlorine wetting binders gave irreproducible results and we have chosen not to report the data here.

Commercial iron particles have a ceramic surface coating that serves to inhibit sintering during particle synthesis and also passivates the particles against corrosion. The particles used in this work had very different ceramic compositions. MP-1 was aluminum-rich with very little silicon, while MP-2 was silicon-rich with no detectable aluminum. Adsorption isotherms for adsorption of AQPU-15 from THF solution showed a very different behavior for the two particles. These two particles had different specific surface areas and for comparison the amount of polymer adsorbed was expressed per specific area of the particle. MP-1 had a Langmuir capacity, $A = 6.00 \pm 0.00 \text{ mg/m}^2$ and a Langmuir affinity coefficient, $B = 0.98 \pm 0.00$, while MP-2 had $A = 4.14 \pm 0.35 \text{ mg/m}^2$ and $B = 0.77 \pm 0.21$. AQPU-15 had a preferential affinity towards MP-1, which had an aluminum-rich surface oxide.

Metal particle tapes prepared using amine quinone polymers and commercial metal particles were exposed to different corrosive environments to study the corrosion protection capability of these polymers. For comparison purposes, MP tape samples containing commercial polyvinylchloride wetting binders were also studied. Two accelerated corrosion conditions, pH 2 aqueous buffer and 80 $^{\circ}\text{C}$ and 80% relative humidity were selected. The extent of corrosion of iron pigment was determined by measuring the relative loss in bulk magnetic properties as a function of time exposed to the corrosive conditions. Figure 2 is a plot of relative saturation magnetization as a function of exposure time. The MP sample made with commercial polyvinyl chloride wetting binders, PVC-1 and PVC-2, completely corroded (complete loss of bulk magnetic properties) after only 2 h exposure to pH 2 buffer. The MP samples containing amine-quinone polymers showed excellent stability in pH 2 aqueous buffer solution for many hours. A similar, though less, dramatic trend in corrosion protection was found for MP samples exposed to 80 $^{\circ}\text{C}$ and 80% relative humidity, Fig. 3. MP tapes containing amine-quinone polymers showed better retention

FIG. 2. Plot of relative saturation magnetization as a function of exposure time for MP tapes exposed to pH 2.0 aqueous buffer.

of magnetic properties than MP tapes prepared from the polyvinylchloride wetting binders. Among the amine-quinone polyurethanes, MP samples prepared from AQPU-15 (having 40% AQM-1 and the highest affinity for the particle surface) showed the best corrosion protection, while AQPU-13 (having 20% AQM-1 and a lower affinity for the particle surface) showed least corrosion protection. This better coverage of particle surface afforded by AQPU-15 led to better protection of particle surface from corrosive pH 2 aqueous buffer solution.

MP samples containing AQPU-15 and either MP-1 or MP-2 showed very different corrosion behavior when exposed to pH 2 buffer, Fig. 4. MP-1 particles having an aluminum-rich surface and a higher Langmuir capacity for AQPU-15, had an excellent stability against corrosion. MP-2 particles having a silicon-rich surface and a much lower Langmuir capacity for AQPU-15, completely corroded after 2 h exposure. This difference in the ability of the amine-quinone polymer to protect the iron particles from corrosion

FIG. 3. Plot of relative saturation magnetization as a function of exposure time for MP tapes exposed to 80 °C and 80% relative humidity.

FIG. 4. Plot of relative saturation magnetization as a function of exposure time for MP tapes exposed to pH 2.0 aqueous buffer.

may be due to the difference in surface sites, arising from the different ceramic coatings. However, we can not rule out the possibility that this difference may be due to the presence of Co and Ni in MP-2, which may make this particle intrinsically more susceptible to corrosion. This question will be addressed when we obtain iron particles, having the same ceramic surface chemistry, but different levels of Co and Ni.

Our early success in inhibiting the corrosion of commercial iron particles, MP-1, by using amine-quinone polymers led us to expect that amine-quinone polymers would protect all grades of iron particles from corrosion. The results clearly showed that both the adsorption behavior and corrosion protection were influenced by the composition of metal particles. Clearly the amine-quinone polymers have a preference for iron particles having aluminum in their surface ceramic layer.

Synthesis and magnetic properties of electrodeposited metal particles on anodic alumite film

Xiaohua Bao,^{a)} Feiyue Li, and Robert M. Metzger

Department of Chemistry and Center for Materials for Information Technology, University of Alabama, Tuscaloosa, Alabama 35487-0209

Elongated metal particles have been prepared by depositing transition metals into the pore channels of anodic aluminum oxide (alumite), with well-defined pores that build up into uniform and parallel channels. The highest coercivity for freshly prepared α -Fe particles in the alumite substrate reached 2700 Oe in the easy direction. The remanence curves of alumite films containing electrodeposited metals (Fe and Co) were measured to study the magnetostatic interaction of the particles. The possible reversal mechanisms of the metal particles in the alumite substrates were examined by the rotational hysteresis integral and the angular variation of the coercivity. © 1996 American Institute of Physics. [S0021-8979(96)06808-6]

I. INTRODUCTION

Needle-shaped α -Fe or metal alloy particles, prepared by electrodeposition of metal into the parallel micropores of anodized aluminum substrate, have been considered as potential candidates for both perpendicular magnetic recording media^{1,2} and high-quality particulate magnetic media.³ Anodizing an aluminum sample in acidic solution (sulfuric, oxalic, chromic, or phosphoric acids) forms a thin layer of well-defined microporous structure, ideally consisting of hexagonal close-packed cells (Fig. 1). The shape of the particles assembled in the film ensures a large perpendicular anisotropy. The pore density and the pore diameter of the sample depend upon the acid used and the applied anodizing voltage. The micropores formed by anodization can also be widened to any desired value, by treating the sample with dilute phosphoric acid for different times. The metal particles formed by electrodeposition can be freed from the substrate by dissolving the alumite with a mixture of chromic acid and phosphoric acid.

Magnetostatic interactions among the magnetic particles influence their magnetization reversal. Several theoretical models for magnetic particle interactions have been studied.⁴⁻⁶ In an electrodeposited anodic alumite sample the metal particles are embedded in parallel pore channels, which provides a simple geometry for theoretical calculations. The perpendicular anisotropy energy of an Fe-electrodeposited alumite film was calculated theoretically by Masuda⁷ (who studied hexagonal arrays of cylinders 1–1.3 μm long, 33–57 nm diameter, 115 nm distant center to center) and by Daimon *et al.*⁸ In this article, the magnetostatic interaction of the particles was studied by measuring the remanence curves; the reversal mechanisms of the particles were examined by the rotational hysteresis integral and the angular variation of the coercivity.

II. EXPERIMENTAL DETAILS

An aluminum sheet ($1 \times 2 \times 0.025 \text{ cm}^3$) was treated with 5% NaOH solution at 60–70 °C, then neutralized in 50%

HNO_3 and rinsed with deionized water. This surface-treated aluminum sample was anodized at 50 V in 15% H_2SO_4 solution at room temperature, using another Al sheet as cathode. The pores of the anodic alumite were widened by immersing the sample in dilute phosphoric acid (0.085 M). Transition metals (Fe and Co) were electrodeposited by ac electrolysis into the pore channels by using the corresponding electrolyte (either 50 g/L $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ or 30 g/L CoSO_4 , plus 25 g/L boric acid). Metal deposition was carried out at 16 V, 60 Hz, with a graphite counterelectrode.

The morphologies of the alumite films and the metal particles were observed by a transmission electron microscope (Hitachi H-800 200 kV TEM). The magnetic properties of the metal electrodeposited films and the metal particles were measured in a vibrating sample magnetometer (digital measurement systems VSM) with a maximum applied field of 14 kOe.

III. RESULTS AND DISCUSSION

The cell diameter and the pore diameter of the anodic alumite sample (anodized in 15% H_2SO_4), measured from a TEM micrograph, were 35 and 18 nm, respectively. A typical region of the anodized alumite film is shown in Fig. 2. TEM images of α -Fe particles, freed from the substrate by dissolving the alumite with $\text{H}_3\text{PO}_4/\text{H}_2\text{CrO}_4$, were also obtained (Fig. 3); the average lengths were 250–500 nm (depending on deposition times); the diameter was 16 nm. All of the

50 nm

FIG. 2. TEM image of an anodized alumite film, showing the open pores (light areas).

metal (Fe and Co) electrodeposited anodic alumite samples showed strong perpendicular anisotropy. Typically, coercivities in the easy direction are (for fresh samples) $H_c=2300\text{--}2700$ Oe for α -Fe, and 1400 Oe for Co. To our knowledge, the coercivity of 2700 Oe is the highest value measured for pure α -Fe particles.

Oxidation in the channels occurs slowly: α -Fe samples that are several days old have $H_c=2100\text{--}2200$ Oe. When fresh α -Fe electrodeposited samples were heated in boiling water (to seal the pores), or reduced under hydrogen gas at 450°C , their coercivity after several days was 300–400 Oe higher than that of untreated samples.

In an attempt to make high-moment acicular $\alpha''\text{-Fe}_{16}\text{N}_2$ containing particles, α -Fe particles imbedded in the alumite matrix (the bottom Al metal sheet was removed by treating with Br_2/MeOH) were nitrided under ammonia and hydrogen mixed gas at 700°C and quenched by immersion in liquid nitrogen.⁹ The nitrided sample was characterized with VSM and powder x-ray diffraction: $\gamma'\text{-Fe}_4\text{N}$ was detected for high $\text{NH}_3:\text{H}_2$ ratios, but no $\alpha''\text{-Fe}_{16}\text{N}_2$ phase has been detected so far in the nitrided samples.

The remanence curves of these samples were measured to study the particle–particle interactions in the films. Fig-

FIG. 3. TEM image of α -Fe particles (length=500 nm, diameter 16 nm) freed from the substrate by dissolving the alumite with $\text{H}_3\text{PO}_4/\text{H}_2\text{CrO}_4$.

FIG. 4. Modified Henkel plots of alumite samples with pores filled with electrodeposited Fe (dc erase and ac erase; the coercivity, squareness, and switching field distribution for the sample are shown in the box).

ures 4 and 5 show the modified Henkel plots (δI vs applied field H) of the Fe and Co containing alumite samples, respectively; δI is defined by $\delta I = I_d - (1 - 2 \times I_r)$, where I_r is the reduced isothermal remanence [i.e., the isothermal remanence divided by $I_r(\infty)$, its value at saturation], and I_d is the reduced dc demagnetization remanence. In general, positive δI values are ascribed to particle–particle interactions which tend to stabilize the magnetized state, while negative δI values come from mutual particle–particle demagnetization.¹⁰ For Fe particles or Co particles in alumite, the modified Henkel plots (Figs. 4 and 5) show that ac erasure can randomize the particle moments, while dc erasure cannot. Since the demagnetization interaction fields were found to be similar for all the samples, they are clearly due to the parallel arrangement of the particles in two dimensions; this also causes a larger switching field distribution (SFD=0.52 for Fe and 0.95 for Co).

The reversal mechanisms of the metal particles in the alumite substrates were also examined by the rotational hysteresis integral [$R = \int (W_r/I_s) d(1/H)$, Fig. 6], where W_r is

FIG. 5. Modified Henkel plots of alumite samples with pores filled with electrodeposited Co (dc erase and ac erase; the coercivity, squareness, and switching field distribution for the sample are shown in the box).

FIG. 6. Plot of the rotational hysteresis integrand $W_r/(I_s \cdot H_c)$ as a function of (H_c/H) , the reciprocal of the applied field H multiplied by the coercivity H_c , for the alumite films electrodeposited with Fe (closed circles) and with Co (open circles). The insets show the values of the rotational hysteresis integral R (0.85 for Fe, 0.56 for Co).

the work per unit volume needed to rotate the sample by 360° in a fixed magnetic field, and I_s is the saturation magnetization, and also by the angular variation of the coercivity (Fig. 7).

FIG. 7. Variation of coercivity H_c and of remanence coercivity H_r with the angle between the particle axis and the applied magnetic field.

TABLE I. Values of R , the rotational hysteresis integral for different reversal models.¹¹

Wall motion	Coherent rotation		Incoherent rotation		
	Stoner-Wohlfarth model		fanning model		curling model
	aligned	random	aligned	random	aligned
4.0	0.415	0.380	1.54	1.02	2.6

For different reversal models the R values can be predicted theoretically, as shown in Table I.¹¹ The measured values $R=0.85$ for aligned Fe particles in alumite (Fig. 6), and $R=0.56$ for aligned Co particles in alumite (Fig. 6) include the particle-particle interactions, and suggest that the reversal mechanism is, to a first approximation, closer to the Stoner-Wohlfarth model ($R=0.41$) than to other models. This assumption is also supported by the angular dependence of the coercivity (Fig. 7).

Lanthanide and boron oxide-coated α -Fe particles

Feiyue Li, Xiaohua Bao,^{a)} and Robert M. Metzger

Department of Chemistry and Center for Materials for Information Technology, University of Alabama, Tuscaloosa, Alabama 35487-0209

Massimo Carbuicchio

INFM, Department of Physics, Università di Parma, Viale delle Scienze, I-43100 Parma, Italy

To increase the coercivity of α -Fe particles, needlelike goethite crystals were first coated with different Ln^{3+} ions ($\text{Ln}=\text{La}, \text{Nd}, \text{Sm}, \text{Gd}, \text{Dy}, \text{Eu}$) plus B^{3+} , then reduced to α -Fe under H_2 . The magnetic moment of the particles depends upon the Ln and B contents and temperature. Both powder x-ray diffraction and Mössbauer spectra indicate the existence of a crystalline FeO phase; the FeO content decreased as the reduction temperature increased. A phase with no hyperfine splitting was also detected in the Mössbauer spectra, which may be superparamagnetic α -Fe or amorphous iron oxide; the amount of this phase decreased as the reduction temperature increased. The temperature dependence of the coercivity of these B- and Ln-coated particles was steeper than for particles coated with silica: this suggests a coercivity mechanism other than shape anisotropy.

I. INTRODUCTION

High-density magnetic recording requires the development of media with ever higher coercivity and magnetic moment. Fine acicular particles of α -Fe or alloys are suitable and widely used media materials. Several methods have been investigated to prepare acicular metal particles: decomposition of carbonyls¹ or oxalates,² reduction of ferrous salts in aqueous solution with NaBH_4 ,³ deposition from the vapor phase,⁴ and the conventional method of reducing acicular goethite (α -FeOOH) particles under H_2 gas.⁵

Miyahara and Kawakami reported a coercivity enhancement of α -Fe particles by a surface coating of Nd and B.⁶ This coercivity enhancement was attributed to a possible coupling between the amorphous iron oxide layer with a special microstructure, and the iron core.⁶ In this article, α -Fe particles were coated with boron and several rare-earth elements; the magnetic properties and the phases present in the samples were studied by powder x-ray diffraction and Mössbauer spectroscopy.

II. EXPERIMENTAL DETAILS

Acicular goethite (α -FeOOH) particles were synthesized by passing air for at least 20 h through an aqueous solution (volume=100 mL) of 0.018 mol $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ and the additives $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ (atom ratio $\text{Ni}/\text{Fe}=0.01$) and NaH_2PO_4 (atom ratio $\text{P}/\text{Fe}=0.01$) mixed with 0.072 mol NaOH . The Ni^{2+} and PO_4^{3-} additives are known to increase the aspect ratio and improve the size distribution of the goethite particles.^{7,8} The particle size and the aspect ratio of the goethite particles depend upon the Ni^{2+} and PO_4^{3-} concentration. After optimizing the reaction conditions (Ni and P contents, dehydration temperature, reduction temperature, and reaction time), the aspect ratio of the goethite particle reached about 17:1; the average particle length was about 0.2 μm .

The goethite particles were coated with different Ln^{3+} ions ($\text{Ln}=\text{La}, \text{Nd}, \text{Sm}, \text{Gd}, \text{Dy}, \text{Eu}$) and B^{3+} (by using the appropriate aqueous solutions of nitrate salts and H_3BO_3), then washed, dried, reduced to α -Fe under H_2 , then slowly exposed to air under toluene. For instance, freshly prepared α -FeOOH particles were dispersed in 100 mL of a solution of $\text{Ln}(\text{NO}_3)_3$ (atom ratio $\text{Ln}/\text{Fe}=0.05$) and of H_3BO_3 (atom ratio $\text{B}/\text{Fe}=0.18$); the pH of the slurry was adjusted to pH 8 with ammonia solution, so that the hydroxides of Ln and B could coat the surfaces of the α -FeOOH particles. The coated particles were dried at 130 °C in air, and then reduced to α -Fe particles by passing H_2 gas at high temperatures (specified below) for 4 h. The coated α -Fe particles were then immersed in toluene and dried in air at room temperature. A sample coated with silica (instead of borides and lanthanides) was also prepared, for comparison.

The morphologies of particles (goethite and α -Fe) were observed by transmission electron microscopy (Hitachi H-800 TEM). The magnetic properties of the metal particles were measured on a vibrating sample magnetometer (Digital Measurement Systems) with a maximum applied field of 14 kOe. The presence and the contents of different phases in the reduced particles were identified by powder x-ray diffraction (Rigaku DXG-2B) using $\text{Cu } K_\alpha$ radiation and by transmission Mössbauer spectroscopy.

FIG. 2. Transmission electron micrographs of α -Fe particles coated with La and B oxides, after reduction in H_2 gas at (a) 480 °C (b) 550 °C, and (c) 650 °C. Sintering increases with increasing reduction temperatures.

III. RESULTS AND DISCUSSION

The coercivity of the rare-earth and boron-coated α -Fe particles varied from 1750 to 1950 Oe. Varying the rare-earth elements did not have a large or systematic effect on the magnetic properties (see Table I). The magnetic moment of the particles depends slightly on which lanthanide was used (see Table I), and strongly on the reduction temperature: Fig. 1 shows the magnetic moment (σ_s) and coercivity (H_c) of La and B-coated particles as a function of the reduction temperature. As the reduction temperature increased from 480 to 580 °C, the coercivity of the particles increased from 1750 to 2100 Oe. When the reduction temperature was further increased to 650 °C, the coercivity of the sample dropped to 1250 Oe, because significant particle sintering was seen by TEM (see Fig. 2) for particles reduced at 650 °C. The magnetic moment of the particles increased monotonically with the reduction temperature. The other lanthanide coatings were not studied as a function of reduction temperature.

The existence of a crystalline FeO phase was confirmed by both powder x-ray diffraction (see Fig. 3) and Mössbauer spectra (see Fig. 4) of the La and B-coated particles. In particular, the Mössbauer spectra show a four-line contribution due to nonstoichiometric ferrous oxide: two absorption lines at 1.47 and 1.30 ± 0.01 mm/s (with respect to α -Fe), due to Fe^{++} ions in stoichiometric wustite structure, and two at 0.80 and 0.43 ± 0.01 mm/s, due to Fe^{++} ions located near clusters of vacancies.⁹ The FeO content decreased as the reduction temperature increased (see Fig. 5), which is consistent with the increase in magnetic moment. A phase with no hyperfine splitting was also detected in the Mössbauer spec-

FIG. 4. Transmission Mössbauer spectrum of La- and B-coated samples reduced at different temperatures.

tra (see Fig. 4), which may be γ -austenite (unlikely), isolated superparamagnetic α -Fe, or an amorphous iron oxide in the passivation layer. The relatively small amount of this phase decreased slightly as the reduction temperature increased (see Fig. 5).

The temperature dependence of the coercivity of these B- and La-coated particles was steeper than for Si-coated

FIG. 5. Mössbauer Fe atom fraction of α -Fe, FeO, and the unknown phase, as a function of the sample reduction temperature.

FIG. 6. The temperature dependence of the coercivity of B- and La-coated particles and Si-coated particles.

particles, for which shape anisotropy is thought to be dominant (see Fig. 6): this suggests that for the B- and La-coated particles the coercivity may be determined by surface anisotropy rather than by shape anisotropy.

In our laboratory, α -Fe particles coated with silica, and prepared by reduction in H_2 at around 400–450 °C have typical moments of 120 emu/g and coercivities of up to 2000 Oe; they tend to sinter at around 500 °C. The Ln oxide-B oxide particles prepared here achieve maximum coercivity of 2000 Oe and a moment of about 75 emu/g at the optimum reduction temperature of 580 °C: therefore equivalent coercivities (but lower moments) are attained using higher reduction temperatures and tolerating higher sintering temperatures than Si-coated particles.

IV. CONCLUSION

Replacing the silica coating of α -Fe particles by a coating of boron and any lanthanide requires higher reduction temperatures and provides a small gain in coercivity. The relatively high coercivity even at low reduction temperatures suggests that the coercivity is not simply due to shape anisotropy.

Time effects in exchange anisotropy-affected metal-evaporated tapes

G. Bottoni, D. Candolfo, and A. Cecchetti

INFM-Dipartimento di Fisica, Università, 44100 Ferrara, Italy

The time-dependent magnetic behavior in metal evaporated tapes for high-density magnetic recording is studied at low temperatures, where the coupling between the ferromagnetic Co and the antiferromagnetic CoO, in the obliquely evaporated CoNiO film, induces a unidirectional exchange anisotropy, and it is compared with the effects obtained at room temperature, where no coupling occurs. At low temperature a contraction of the hysteresis loop as a function of the number of repeated cycles N is observed, with a remarkable decrease of the measured coercive field. No contraction occurs at room temperature. The time dependence of the magnetization is larger at low temperatures, with increase of magnetic viscosity and thermal fluctuation field, than at room temperature. The observed anomalous increase of thermal instability of magnetization and coercivity with the decrease of the temperature is imputed to the presence of exchange coupling between the ferromagnetic and antiferromagnetic phases at low temperature and to the effect that such coupling can exert on the reversal of the magnetization in the ferromagnetic grains. © 1996 American Institute of Physics. [S0021-8979(96)07308-6]

I. INTRODUCTION

Metal-evaporated (ME) tapes are Co-Ni obliquely evaporated thin films, which are considered among the most notable of the high density magnetic storage media, and which are now used in high-band 8 mm video cassettes. The tape consists of one or more layers where Co (80%) and Ni (20%) fine ferromagnetic particles are aligned in columns with an angle to the film plane. The deposition takes place in the presence of a flow of oxygen gas, which has a number of beneficial effects on the film properties and on the preparation process, among which are the improvement of coercivity, corrosion resistance and signal-to-noise ratio.^{1,2} The presence of oxygen during the film deposition gives rise to the formation of oxides of the metals, primarily CoO, among the ferromagnetic grains and in the film surface layers. The CoO is antiferromagnetic with a Néel temperature practically coinciding with room temperature ($T_N=293$ K). Below this temperature, the effect of the coupling between the ferromagnetic Co and the antiferromagnetic CoO is significant, and we observed a shift of the hysteresis loop along the field axis in the tapes cooled from room temperature to lower temperatures in the presence of an applied magnetic field or in the remanent state³ (no displacement of the hysteresis occurs when the tape is cooled demagnetized and in zero field). We observed also an anomalous behavior of these ME tapes at low temperature in the presence of rotational magnetic field, with a monotonic increase of the rotational hysteresis energy losses with the applied field, which do not show any tendency to decrease at least up to fields as high as 18 kOe (i.e., substantially larger than the anisotropy field of these materials).⁴ These effects are originated in the exchange coupling between the ferromagnetic and antiferromagnetic phases, which gives rise to the unidirectional "exchange anisotropy" when the system is cooled through the Néel temperature of the antiferromagnet, and which was observed in different systems, since 1956.⁵ The presence of exchange anisotropy in ME tapes was proved also by the analysis of the torque curves, which show a superposition of uniaxial and unidirectional anisotropies at low temperatures.⁴

In this work, we have studied the time-dependent magnetic behavior of these ME tapes at low temperatures, where the two magnetic phases are exchange coupled with the macroscopic effects we described, and we have compared it with the behavior at room temperature, where no coupling occurs.

II. EXPERIMENT

Several types of different commercial ME tapes have been analyzed. The behavior is similar in all samples and in this paper two of them have been chosen to represent the magnetic behavior of all them. The two tapes are indicated with the letters A and B. The hysteresis loops have been measured with a total sweep time of 5 min in all the reported experiments. At room temperature the hysteresis is symmetrical with coercivity $H_c \approx 1100$ –1150 Oe and saturation magnetization about 500 emu/cm³. When cooled from room temperature in presence of an applied field ($H=10$ kOe) or in the remanent state the hysteresis is displaced, with different values of the coercivities in the two branches of the hysteresis loop, H'_c and H''_c . At 80 K $H'_c = 3350$ Oe (A and B tapes), $H''_c = 2420$ Oe (A) and 2020 Oe (B). When the demagnetized tapes are cooled in zero field, no displacement of the hysteresis occurs, and $H'_c = H''_c = 2600$ –2500 Oe. The remanent magnetization lightly decreases with the decrease of temperature: at 295 K $M_r \approx 400$ emu/cm³, at 80 K $M_r \approx 380$ emu/cm³.

The above-reported values are the coercivities obtained in the first cycle after cooling. If the cycle at 80 K is repeated, the magnetization values change: the hysteresis loops are not superimposed, but they show a contraction which increases with the number of cycles N . The absolute values of both the coercivities, H'_c and H''_c , decrease with increasing N . The H_c variation rate decreases when the number of cycles increases, and the contraction seems to proceed towards a saturation. Figure 1 shows the hysteresis contraction of tape A in the first five cycles after cooling. The observed effect is large: the variation $\Delta H'_c \approx 700$ Oe after 15 cycles. The lower coercivity H''_c exhibits a smaller decrease: $\Delta H''_c$

FIG. 1. Hysteresis loops of tape A at 80 K in the first five cycles after cooling. N is the number of cycles.

$\cong 200$ Oe (in 15 cycles). On the contrary, no noticeable contraction occurs in repeated cycles at room temperature.

The dependence of H_c on the number of cycles N is almost linear with $1/\sqrt{N}$, as it is shown in Fig. 2, and it can be described by the equation:⁶

$$H_c(N) = H_c(\infty) + \frac{K}{\sqrt{N}}, \quad (1)$$

where K is a constant and $H_c(\infty)$ should be the value of coercivity obtained after an infinite number of cycles. As we see in Fig. 2, $H_c'(\infty) \neq H_c''(\infty)$ in both tapes, which means that, even when deducted this contraction effect, a dissimmetry between the coercivities in opposite directions persists. This indicates the different origin of the hysteresis displacement (exchange anisotropy) than that of the coercivity reduction with repeated cycles, which we can impute to time effects.

In the same ME tapes we also measured the time dependence of the magnetization: the samples were saturated with the application of a strong magnetic field, then an opposite field H was applied and the decrease of the magnetization with time in the presence of a constant field H has been measured. The magnetization decay has been evaluated both at room temperature and at 80 K. At this low temperature,

FIG. 2. Coercive fields in opposite directions of tapes A and B as a function of $1/\sqrt{N}$, with N number of cycles.

FIG. 3. Magnetization decay of tape A at 295 and 80 K (I: tape cooled demagnetized in zero field, II: tape cooled in presence of magnetic field).

the measurement has been performed in tapes cooled demagnetized in zero field (I) and in tapes cooled in presence of a magnetic field (II). Figure 3 shows the obtained magnetization decay of tape A in the three cases. Tape B and all of the other ME tapes we measured showed similar behavior. The decay is much faster at 80 K than at room temperature, and the samples cooled in the presence of H (shifted loops) have larger decay than the samples cooled as demagnetized (symmetrical loops). This result is surprising: at low temperature the thermal energy effect is larger than at higher temperature. As a consequence the coefficient of magnetic viscosity S ,⁷ which is the rate of variation in the dependence of M on $\ln(t)$, increases when the temperature decreases. Figure 4 reports the dependence of S on reduced field at room temperature and 80 K. The maximum value of S , which is reached at applied field $H \cong H_c$, increases from ~ 2.5 emu/cm³ at room temperature to values as high as ~ 16 emu/cm³ at 80 K. From the magnetic viscosity it is possible to deduce the thermal fluctuation field $H_f = S/\chi_{irr}$, the magnetic field which will have on the magnetization the same effect of the thermal agitation.⁸ Also H_f is larger at 80 K than at room temperature, as it is shown in Fig. 5, and it increases from ~ 10 to

FIG. 4. Magnetic viscosity vs reduced applied field of tape A at 295 and 80 K.

FIG. 5. Thermal fluctuation field vs reduced applied field of tape A at 295 and 80 K.

~100 Oe. The irreversible susceptibility χ_{irr} decreases from ≈ 0.23 to ≈ 0.17 emu/cm³ Oe cooling from 295 down to 80 K.

III. DISCUSSION

The experimental results show that in the ME tapes the thermal stability of the magnetization is weakened by the decrease of temperature, with increase of magnetization decay, magnetic viscosity and thermal fluctuation field. This evolution is accompanied by a contraction of hysteresis in repeated cycles at low temperatures, with a diminishing of coercive field in successive cycles, which does not occur at room temperature.

As discussed above, in these Co-Ni-CoO systems an exchange anisotropy appears at low temperatures, and the physical origin of this particular property can perhaps explain the unusual increase of time effects with decreasing temperature. The exchange anisotropy is due to the exchange coupling between the adjacent layers of ferromagnetic and antiferromagnetic phases. When the system is cooled through the Néel temperature of the CoO in the presence of a magnetic field, the consequent orientation of the spins in the antiferromagnet gives rise to the unidirectional anisotropy in the coupled ferromagnetic grains.

At room temperature, and in general above the Néel temperature of the antiferromagnet, no magnetic order exists in the Co oxide, and thus no exchange coupling with the ferromagnet. Below the Néel temperature, the CoO is antiferromagnetically ordered, but the action of an applied field, in conjunction with that of the thermal energy, opposes the antiparallelism of the elementary magnetic moments, which can result in partial misalignment (canting). The magnetic spins of the adjacent layers of ferromagnetic Co grains which are exchange coupled with the canted spins of the antiferromagnet are also misaligned, even with respect to the other layers of magnetic moments in the ferromagnetic Co grains. Such region of different magnetic orientation can act as centers of nucleation for the reversal of the magnetization in the particles. In such condition the magnetization switching is modified and made easier than it would be if such misaligned regions did not exist. Consequently the particles are magnetically less stable: the total magnetization of the material markedly decreases with the time and the coercivity is progressively reduced.

The macroscopic effects of this evolution of magnetization reversal mode therefore are just the experimental results we observed: at low temperature, where Co is exchange coupled with CoO, the magnetization decay and viscosity will be anomalously larger than at room temperature and the coercivity in successive multiple cycles will decrease, as a further consequence of the enhancement of time effects on the magnetization.

The archival stability of metal evaporated tape for consumer digital VCRs

Seiichi Onodera, Tsutomu Takeda, and Takahiro Kawana

Sendai Technology Center, Sony Corporation 3-4-1 Sakuragi, Tagajo-shi, Miyagi-ken 985, Japan

A new metal evaporated (ME) tape was released for consumer digital VCRs. It has greatly improved its recording characteristics and durability compared with conventional Hi-8ME tape. Demagnetization of the new ME tape has been studied using accelerated and ambient conditions. Demagnetization of saturation magnetization follows the cubic law, and it was found that the estimated archival lifetime is about 60 years. Moreover, we have investigated characteristics such as dropout, carrier-to-noise ratio, and error rate, and we confirmed that the new ME tape has enough stability for practical applications. © 1996 American Institute of Physics. [S0021-8979(96)14108-1]

I. INTRODUCTION

Co-(Ni)-O obliquely metal evaporated (ME) tape has characteristics suitable for high density recording and low noise properties. Consequently, ME tape was introduced into the consumer video market for a high-band 8 mm VCR in 1989.¹

A new metal evaporated tape was released for digital consumer VCRs. Some of its properties such as recording characteristics and durabilities are greatly improved compared with conventional Hi-8ME tape due to material engineering for the magnetic material, and the adoption of a multilayer structure for the magnetic film, and a carbon protective layer applied on the top surface. It shows about 4.5 dB higher output at a wavelength 0.5 μm .²

There are several investigation of metal evaporated tape on its corrosion properties.^{3,4} In this paper, the archival stability of this new metal evaporated tape is discussed particularly in demagnetization, and characteristics needed for practical application in terms of reproduced output, carrier to noise ratio, dropout, and error rate.

II. EXPERIMENTAL PROCEDURE

Magnetic layers were deposited on PET film using web-coater-type vacuum evaporation equipment. The degradation of magnetic properties was measured by a VSM (vibrating sample magnetometer). The applied saturation magnetic field was 1.19 (MA/m). Specimens for the accelerated measurement were kept in each environmental condition up to 100 days as wound cassettes. Table I shows the experimental aging conditions. The recording characteristics were measured with a MIG head with an effective gap length of 0.2 μm , B_s of 1.1 T, a track width of 13 μm , and a head-to-tape relative velocity of 10.2 m/s.

TABLE I. Accelerate experimental condition.

	Temperature (°C)	Humidity (%RH)
I	30	90
II	50	90
III	65	90

III. RESULTS AND DISCUSSION

Figure 1 shows the time aging dependence of demagnetization (ϕ_s) in each accelerating environmental condition, where the ratio of demagnetization is defined as follows: demagnetization $X(\%) = [\Delta\phi/\phi(0)] \times 100$, $\Delta\phi = \phi(0) - \phi(t)$. Each line shows almost the same slope. This slope shows the same values as the Hi-8ME tape we discussed previously.⁵ It indicates that demagnetization (ϕ_s) of the new ME tape for consumer digital VCRs, almost follows the cubic law.⁶ Thus, demagnetization X will be expressed as

$$X^n = kt, \quad n=3. \quad (1)$$

From these results, the constant of rate constant k , is derived, and moreover as shown in Fig. 2, from the relation between $\ln(k)$ and $1/T$ for each condition the activation energy in the Arrhenius part is derived as 1×10^2 (kJ/mol). This value is almost the same as the values in the Hi-8ME tape.⁵ It means that the new ME tape for consumer VCRs has the same temperature dependence as the Hi-8ME tape.

Figure 3 shows the time aging dependence of demagnetization (ϕ_r) in each accelerating environmental condition. The reproduced output depends on the remanent magnetization.

Figure 4 shows long-term demagnetization at room-temperature storage. The demagnetization also nearly fol-

FIG. 1. Time aging dependence of demagnetization (ϕ_s) in accelerating condition.

FIG. 2. Temperature dependence of the logarithmic rate constant.

FIG. 5. Magnetization dependence of reproduced output.

FIG. 3. Time aging dependence of demagnetization (ϕr) in accelerating condition.

FIG. 6. Time aging dependence of dropout.

FIG. 4. Time aging dependence of demagnetization in ambient condition.

FIG. 7. Time aging dependence of carrier-to-noise ratio.

FIG. 8. Error rate dependence of carrier-to-noise ratio.

lows the cubic law like in the accelerated environmental conditions and Hi-8ME in long-term storage at room temperature.

In order to estimate the archival life, we examined the relation between demagnetization and the decrease of reproduced output. Figure 5 shows the effect of the decrease in remanent magnetization on reproduced output at recording wave lengths of 1 and 0.5 μm , respectively. The reproduced output is normalized to the initial value of the tape. A linear decrease in reproduced output in dB was observed against the decrease of remanent magnetization. From Figs. 4 and 5, we can estimate the archival lifetime in ambient atmosphere for a decrease in reproduced output of -1 dB at each recording wavelength. At 0.5 μm recording wavelength, the lifetime has been estimated to be about 60 years at room temperature.

On the other hand, characteristics for reliability in practical application such as dropout, carrier-to-noise ratio, and error rate are also important matters. We describe the changes of these properties at a typical condition of 30 $^{\circ}\text{C}$, 90%.

Figure 6 shows an increase in dropout number. The dropout is measured by SHIBASOKU VH06AZ, as the number of defects defined by a threshold of 10 μs in length and -6 dB in output, per minute in a recording wavelength is

about 1 $\mu\text{m}(fn/2)$. With the passage of storage time, the number of dropouts increases slightly but that number is less than the specification for consumer digital VCRs.

Figure 7 shows the time aging dependence of the carrier to noise ratio. Carrier frequency is around 10 MHz (recording wave length = 1 μm , RBW = 30 kHz, VBW = 300 Hz). The noise level is defined as the average of the amplitudes in two frequencies which are ± 2 MHz from the carrier frequency. The carrier to noise ratio is about 56 dB, and it decreases slightly with increasing storage time. The decrease in reproduced output is the dominant factor for this result, and the increase of the noise level is not significant through the storage.

The effect of the decrease in carrier-to-noise ratio which will be made to the error rate was investigated, as shown in Fig. 8. Every decreased carrier-to-noise ratio was produced by adding white noise to the reproduced signal. From this result, the error rate will change as the carrier-to-noise ratio change.

IV. CONCLUSION

It was found that the demagnetization (ϕ_s) of a new ME tape for consumer digital VCRs follows the cubic law, by measurement at accelerated and ambient conditions. The Arrhenius activation energy was determined to be 1×10^2 (kJ/mol). This is the same value that is determined for the Hi-8ME tape. The estimated lifetime at ambient conditions to decrease the reproduced output for -1 dB ($\lambda = 0.5 \mu\text{m}$) is about 60 years. The degradation of carrier to noise ratio with increasing storage time is mainly caused by the decrease of reproduced output. For a 4 dB change in carrier to noise ratio, the change in error rate will be about 1 decade. A sizable increase in dropouts with storage time was not observed; consequently, this new ME tape is reliable enough for practical applications.

Effects of Cr_2O_3 or Y_2O_3 doping in barium ferrite thin-film medium for high-density recording

Y. J. Chen and M. H. Kryder

Data Storage Systems Center, Dept. of Electrical and Computer Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The effects of Cr_2O_3 or Y_2O_3 doping on the surface morphology and magnetic properties in barium ferrite thin films have been studied. Thin films were deposited by co-sputtering a barium ferrite target with a Cr_2O_3 or Y_2O_3 target. The deposited amorphous films were homogenized at a temperature of 600 °C for over 10 h followed by annealing at 800 °C in a tube furnace. It was observed that, whereas stoichiometric barium ferrite shows 5000 Å×500 Å acicular grainlike features, films doped with Cr_2O_3 or Y_2O_3 had equiaxed topographic features with an average size of 500 Å. Magnetic studies showed that the coercivity of the doped films was over 3500 Oe and was larger than that of stoichiometric films. A weak magnetostatic interaction was found in all the films. Studies of the magnetic after effect indicated excellent thermal stability in all the films. © 1996 American Institute of Physics. [S0021-8979(96)06908-2]

I. INTRODUCTION

The goal of achieving areal density of 10 Gb/in.² and beyond in magnetic recording imposes many challenges on the recording medium. The medium must have coercivity above 3000 Oe¹ in order to record bits with very narrow transition length. The medium cannot utilize a thick overcoat for protection from mechanical wear or chemical erosion because of the demand of lower flying height by the recording head. The signal-to-noise ratio at such high recording density requires that the grains of the recording medium be less than 100 Å in size, and yet magnetically isolated from each other to minimize the transition noise.

Barium hexaferrite thin-film recording media are promising for this application. Stoichiometric barium ferrite thin films typically have coercivity of 3000–4000 Oe. The mechanical hardness and chemical stability of barium ferrite may furthermore eliminate the need for a protective overcoat. The magnetic interactions between grains in barium ferrite thin films are believed to be magnetostatic.² Magnetostatic coupling usually gives rise to lesser transition noise than does exchange coupling, however stoichiometric barium ferrite films have grain sizes of 3000–5000 Å, which is too large to achieve reasonable SNR in high-density magnetic recording.

CoTi doping in barium ferrite thin films was investigated by Sui *et al.*³ and Wong *et al.*⁴ It was observed, however, that CoTi doping reduced not only the grain size, but also the coercivity. In their study, a CoTi doped film which had an average grain size of 160 Å was found to have a coercivity below 1000 Oe. It is desirable to obtain reduced grain size, but still maintain high coercivity.

Hylton *et al.*,⁵ reported small grain size and high coercivity barium ferrite films by inclusion of small amounts of Cr_2O_3 , yttrium stabilized zirconia (YSZ), ZrO_2 , and other additives. The purpose of the present study is to further pursue the effects of doping on the microstructural and magnetic properties of barium ferrite thin films, particularly when Cr_2O_3 or Y_2O_3 are used as the dopants.

II. EXPERIMENTAL PROCEDURES

The barium hexaferrite films were deposited by rf sputtering in a Leybold Z-650 sputtering system by co-sputtering of two 3 in. targets. A $\text{Ba}_{1.25}\text{Fe}_{12}\text{O}_{19}$ target was used as the primary target. Cr_2O_3 or Y_2O_3 targets were used as the secondary target. In order to achieve as small as 1% volumetric addition of the dopants in the barium ferrite films, the path between the secondary target and the substrate palette was blocked by a plate with an adjustable slot opening. During the sputtering process, oxidized Si substrates on a rotating substrate palette were exposed to the targets alternately. The amount of doping was adjusted by controlling the slot opening and by changing the sputtering powers of both targets. In this study, the sputtering power of the secondary target was fixed at 50 W, and a sputtering power of 75 W or 125 W was used for the barium ferrite target. The total Ar/O₂ gas flow rate was 120 sccm with an O₂ flow rate of 20 sccm. The thicknesses of all the films were 1000 Å.

One batch of the as-deposited amorphous films (A1, B1, C1) was annealed for 15 min in a tube furnace preheated to 800 °C. Another batch of amorphous films (A2, B2, C2) was soaked at 600 °C for 10 h and then annealed at 800 °C for 15 min in the same furnace. The magnetic properties of the films were studied on an alternating gradient magnetometer (AGM). From the magnetic hysteresis loops of the samples, M_s , H_c , and squareness were determined. The doping and sputtering conditions of these films, as well as their magnetic properties, are listed in Table I.

TABLE I. In-plane magnetic properties.

Sample	Dopant	BaFe sputtering power (W)	M_s (emu/cc)	H_c (Oe)	Sq.	S^*
A1	...	75	266	3250	0.65	0.55

B2	Cr_2O_3	75	289	3550	0.70	0.52
C1	Y_2O_3	125	230	3165	0.47	0.34
C2	Y_2O_3	125	238	3210	0.49	0.30

FIG. 1. X-ray diffraction spectrum of sample B2.

III. RESULTS

Typical X-ray diffraction patterns shown in Fig. 1 indicate that the majority of the grains have their c axes oriented randomly in the plane of the films as suggested by the strong (110) and (220) peaks. However, other peaks appearing in the diffraction pattern indicate a considerable volume of the film with out-of-plane orientation of the c axis.

The surface morphologies of the films were characterized using an atomic force microscope (AFM). It was observed that the samples which were annealed at 800 °C had acicular grainlike features typically 5000 Å in length. The AFM image of sample A1 is shown in Fig. 2. In samples B1 and C1, which were doped with Cr_2O_3 and Y_2O_3 , respectively, similar equiaxed features were observed.

The AFM images of the doped samples, which had been soaked at 600 °C prior to annealing at 800 °C, showed a very different surface morphology. Sample B2 has only fine equiaxed features, as indicated in Fig. 3. The average feature size of sample B2 is about 500 Å. Sample C2 has even finer

FIG. 2. AFM image of the undoped sample A1 which was annealed at 800 °C.

FIG. 3. AFM image of the Cr_2O_3 doped sample B2 which was soaked at 600 °C for 10 h prior to annealing at 800 °C.

equiaxed features yet there are still some traces of large acicular grainlike features. The surface morphological structure of the undoped sample A2, which had been soaked at 600 °C prior to annealing at 800 °C, remained similar to the surface morphology of sample A1.

The in-plane hysteresis loops of the films were measured using an AGM. The results are listed in Table I. The coercivity of sample B2 is 3550 Oe, about 10% greater than samples A1 or B1. The squarenesses of samples A1, A2, B1, and B2 range from 0.65 to 0.7, whereas the squareness of samples C1 and C2 is approximately 0.5.

Values of $\Delta M^{6,7}$ were also measured for the films. The results for samples A1 and B2 are plotted in Fig. 4 as a function of applied field. Both samples show a small positive interaction among the grains at low field and a small negative interaction at high field.

The thermal stability of the films was studied by measurements of the magnetic viscosity⁸ at room temperature. A

FIG. 4. Plots of ΔM for samples A1 and B2.

FIG. 5. Magnetic viscosity $S = -dM/d \ln t$ plotted vs field for samples A1 and B2.

12 000 Oe magnetic field was first applied to saturate the samples and was subsequently reversed in direction and held at H during the measurement. The process was repeated for various values of H . The time dependences of the magnetization were then measured for up to 200 s. The magnetic viscosity S ($=|dM/d \ln t|$) was extracted through linear regressions of the M vs $\ln t$ plots. There were small variations of S in different time regimes. The linear regressions of data were carried out at 100 s for consistency. The data of samples A1 and B2 are shown in Fig. 5. Both samples have a similar field dependence of magnetic viscosity. There is no thermal decay observed at $H=0$ for either sample. The magnetic viscosity S of sample B2 is less than 0.2 emu/cc at $H < 2000$ Oe.

IV. DISCUSSION AND CONCLUSIONS

The imperfection of the c -axis in-plane orientation as indicated by the x-ray diffraction spectra in Fig. 1 may be due to the high sputtering power used on the barium ferrite target. Sui *et al.*⁹ previously showed that the c -axis in-plane orientation could be enhanced by using low sputtering power. However, low sputtering power results in a low sputtering rate of about 2 Å/min for barium ferrite and a long sputtering time >8 h for a 1000 Å thick film.

From the studies of the topographic structure, it is concluded that doping of barium ferrite with Cr_2O_3 or Y_2O_3 , followed by proper annealing, results in changes in the surface morphology of the films. The doped and annealed samples exhibit a finer and more equiaxed surface morphology than the undoped samples. This surface morphology is in

fact very similar to the grain structure observed previously by transmission electron microscopy (TEM) in CoTi doped samples,⁴ and it is believed that the Cr_2O_3 and Y_2O_3 doped films also have a fine grain structure, although this has not yet been confirmed by TEM.

The small increase of H_c in both the Cr_2O_3 and Y_2O_3 doped films contrasts with the reduction in H_c previously observed in CoTi doped films.⁴ CoTi doping is known to reduce the anisotropy of barium ferrite. Hence the reduction of H_c in that case is expected. The increase in coercivity for Cr_2O_3 and Y_2O_3 doping may be related to the observed changes in topography, actual changes in grain size or shape,¹⁰ or to nonmagnetic phases introduced by the Cr_2O_3 or Y_2O_3 .

The values of squareness of samples A1, A2, B1, and B2 bear the characteristics of 2D randomly oriented single domain particles. The smaller values of squareness of samples C1 and C2 are believed to be caused by the more random c -axis orientation, due to the greater sputtering power used as indicated by x-ray diffraction spectra. It is noted that the squareness value of 0.5 corresponds to the squareness expected from a random array of noninteracting particles.

The small positive portion of the ΔM curve is believed to be caused by positive magnetostatic interaction between stacked grains. The values of ΔM become negative at larger fields, presumably because of negative magnetostatic interactions of adjacent grains. The transition occurs when about half of the grains or grain clusters have switched their magnetization direction.

The small thermal decay found in the magnetic viscosity measurements indicates that the films are thermally stable.

Ba-ferrite (BaM) thin films were prepared by both a facing targets sputtering (FTS) system and dc magnetron sputtering (DCMS) at room temperature. They were successively annealed to crystallize. The films prepared by FTS system were crystallized at 650 °C, while those prepared by DCMS system were crystallized at 700 °C. Saturation magnetization, coercivity, and squareness ratio of the films prepared by FTS are 210 emu/cc, 3.3 kOe, and 0.7 in perpendicular direction, respectively, after the annealing at 650 °C. It was found that oxidized Fe is partially reduced to metallic Fe by high-temperature annealing. © 1996 American Institute of Physics. [S0021-8979(96)07408-2]

I. INTRODUCTION

High-density recording medium should have an excellent mechanical durability as well as moderate hard magnetism. Oxide films have a big advantage in chemical stability and mechanical durability as compared with a metal thin film. The authors have been studying hexagonal Ba-ferrite (BaM) films prepared by a sputtering¹ and sol-gel method² for high-density perpendicular magnetic recording media. In order to prepare BaM films with *c*-axis orientation, the substrate temperature should be elevated to about 620 °C,¹ but such a high temperature is not suitable for the practical fabrication of recording media. The authors have already reported that a Pb addition is effective to lower the substrate temperature to 550 °C.³ It is still recommended to lower the substrate temperature for the practical fabrication. Recently, a few studies on the postannealing effects for amorphous BaM films prepared by a conventional diode sputtering system have been reported.^{4,5}

In this study, in order to develop a new fabrication technique for BaM thin films, BaM ferrite films have been prepared at room temperature by using both a facing target sputtering (FTS) system and a conventional dc magnetron sputtering (DCMS) system at room temperature. These films were successively annealed in air and their crystallographic characteristics and magnetic properties have been studied.

II. EXPERIMENT

The films were prepared by using a FTS system⁶ and DCMS system at room temperature. In the FTS system, a pair of permanent magnets are installed behind both targets. The magnetic field from these magnets confines the plasma between the targets. Consequently, the films can grow without disturbance from the plasma because the substrate is located out of the plasma.

After evacuating the chamber to a pressure below 2×10^{-6} Torr for both sputtering systems, argon and oxygen gases were introduced and working gas pressure was set at 3 mTorr. The targets used in this study were sintered ferrite disks (8 cm diameter) with stoichiometric composition of BaM (i.e., $\text{BaFe}_{12}\text{O}_{19}$). The substrates were thermally oxi-

dized silicon wafers and the substrate temperature was set at room temperature. The thickness of the films was about 1500 Å.

The deposited films were annealed at 600–900 °C for 5 h in air. The crystal structure was determined by x-ray diffractometry ($\text{Cu } K\alpha$). The chemical shift for Fe in the BaM films were evaluated by x-ray photoelectron spectroscopy (XPS).

III. RESULTS AND DISCUSSION

All of the films prepared by FTS and DCMS systems at room temperature were amorphous. The compositions of the films prepared by the FTS system were $\text{Ba}_{0.9}\text{Fe}_{12}\text{O}_x$, while those prepared by DCMS were $\text{Ba}_{0.6}\text{Fe}_{12}\text{O}_x$. The large deficiency of Ba in the films prepared by DCMS is mainly caused by the bombardment of the high-energy particles, which are recoiled discharge gas atoms and γ electrons emitted from the target.

Figure 1 shows x-ray diffraction diagrams of BaM films annealed at various temperatures (*T_a*). The films prepared by the FTS system were crystallized after they were annealed at

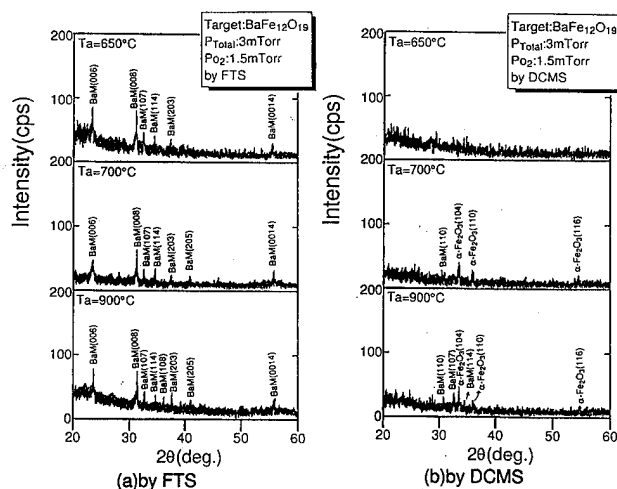

FIG. 1. X-ray diffraction diagrams of the film prepared by FTS (a) and DCMS (b).

FIG. 2. Dependence of saturation magnetization on the annealing temperature.

650 °C, while those prepared by DCMS system were crystallized at above 700 °C of Ta, as shown in Fig. 1. It was found that the crystallization of the films prepared by FTS begins at lower temperature. The diffraction lines for the annealed films prepared by the FTS system are only from the M phase and various planes in hexagonal crystallite are observed. This suggests that magnetic properties of annealed films prepared by FTS are almost isotropic. In contrast with these results the diffraction lines from both the BaM and α -Fe₂O₃ phase are observed for the annealed films prepared by the DCMS system. This is due to the deficiency of Ba in the films as mentioned above.

Figure 2 shows the dependence of saturation magnetization (Ms) for the annealed films on Ta. Ms for the films prepared by the FTS system was almost zero after annealing at 550 °C. The Ms increases from 90 to 210 emu/cc with increase of Ta from 600 to 650 °C and exhibits constant value of 210 emu/cc for further elevation of Ta. The Ms for the films prepared by DCMS increases from zero to 150 emu/cc, with an increase of Ta up to 750 °C, and exhibits almost constant value of 160 emu/cc for further elevation of Ta up to 900 °C. The Ms for the films prepared by DCMS is

FIG. 4. Dependence of squareness ratio on the annealing temperature.

lower than that of the films prepared by the FTS system. This is caused by the coexistence of the nonmagnetic α -Fe₂O₃ phase, as shown in Fig. 1.

Figure 3 shows the dependence of coercivity (Hc) on Ta. The Hc were measured at both in-plane direction (||) and perpendicular direction (⊥). The films prepared by the FTS and DCMS systems show the hysteresis loop after the annealing at Ta at above 600 °C and above 700 °C, respectively. The Hc_{||} and Hc_⊥ have almost same value for the films prepared by the FTS system and increase from about 0.3 to 3.4 kOe with the increase of Ta from 600 to 650 °C and gradually increase with increasing of Ta higher than 650 °C. The Hc_{||} and Hc_⊥ for the films prepared by the DCMS system are from 1.0 to 1.8 kOe and considerably lower than those of the films prepared by the FTS system.

Figure 4 shows the dependence of the squareness ratio (S) in the directions both in-plane and perpendicular to the film plane on Ta. The squareness ratio in both directions for the films prepared by the FTS system increases with the increase of Ta from 600 to 650 °C and exhibits almost constant values at Ta of above 650 °C. The squareness ratio in perpendicular direction is about 0.7 and slightly higher than those of in-plane direction for the films prepared by the FTS system, while those for the films prepared by DCMS take the maximum values of about 0.5 at Ta of 750 °C.

Figure 5 shows the XPS spectra for the films prepared by the FTS system [see Fig. 5(a)] and DCMS [see Fig. 5(b)].

FIG. 5. XPS spectra of the films prepared by FTS (a) and DCMS (b) systems.

FIG. 6. M-H loops for the film prepared by the FTS system after annealing at 650 °C.

Two spectra are observed in as-deposited films. These are from the α -Fe₂O₃ phase. The extra spectrum around 705 eV corresponds to metallic Fe and can be observed for the annealed films. This means that oxidized Fe is reduced to metallic Fe by high-temperature annealing in air. In order to suppress the reduction of oxidized Fe, the oxygen gas pressure should be controlled during the annealing.

Figure 6 shows the M-H loops of the films prepared by the FTS system after annealing at 650 °C. The loops at perpendicular and in-plane directions are almost similar in shape and seem to be composed of two phases. From the x-ray diffraction diagrams, the phase synthesized in the annealed films is only BaM, as shown in Fig. 1. Although it is not clear to date what kind of magnetic phase is necessary for coexistence, reduced metallic Fe, as mentioned above, seems to affect the shape of M-H loops. These shapes should be improved for high-density magnetic recording media.

IV. CONCLUSION
